An Address

FOOD VALUES AND THEIR PRACTICAL APPLICATION IN DIETETICS

L. A. MASON, M.B., M.D., F.R.C.P.
 Lecturer in Dietetics, University of London

THE subject of food values and their practical application in dietetics is one of the most important and interesting in the whole of medicine. It is one which has of late years attracted the attention of the public, and has become a subject of general interest. The importance of the subject is due to the fact that food is the basis of life, and that the quality and quantity of the food which we eat have a profound influence on our health and vitality. The study of food values is therefore a study of the very foundations of human existence. It is a study which has of late years attracted the attention of the public, and has become a subject of general interest. The importance of the subject is due to the fact that food is the basis of life, and that the quality and quantity of the food which we eat have a profound influence on our health and vitality. The study of food values is therefore a study of the very foundations of human existence.

The importance of the subject is due to the fact that food is the basis of life, and that the quality and quantity of the food which we eat have a profound influence on our health and vitality. The study of food values is therefore a study of the very foundations of human existence.

necessary protein can most profitably and economically be provided. Some races have little or no choice in the matter. The Eskimos, for example, live entirely on animal food; they derive their protein and their fats from seal meat and blubber, or such other meat and fat as they may be able to obtain. Yet they live healthily, and are not liable to any special disease as the result of an entirely flesh diet; it is especially noteworthy that they do not develop arterial degeneration, kidney disease, or gout. They derive their calories partly from the fat and partly from the protein, of which 58 per cent. is convertible into glucose if needs be.

At the other end of the scale there are the West African tribes, who live on a diet of flour made from ripe bananas and on the bananas themselves. This one fruit can furnish every requisite, and, provided the bananas are ripe, they contain sufficient amino-acids to give the protein a good biological value. Infants in both these instances are suckled by their mothers; artificial feeding is not practicable. With the exception of this banana diet, no other vegetarian diet provides proteins of good enough biological value. It will be found that milk and eggs must be added. Casein of milk has the highest biological value; it supplies in full measure all the amino-acids essential to life. Growth and full vigour can be maintained on milk—the warriors of the Masai live on milk and blood. Meat comes next in order after milk, kidney ranking first, then liver, then muscle.

Although all the necessary amino-acids may be found in certain cereals, the amounts, in some instances, are inadequate. From the point of view of protein content, therefore, cereals must be supplemented, and it has been found that two cereals do not supplement each other. Milk is a cheaper source of protein than meat, and cheese is especially so. Those who can afford it (and many who cannot) prefer to take the larger part of their protein in meat and eggs, which cost more but are considerably tastier. Perhaps it is not, after all, an extravagance for the adult to prefer the costlier forms of protein. Meat and fish are more gratifying to the palate, and are definitely more satisfying. They may not be so filling at the time, but a meat meal seems to stay longer.

Satiety Value

This feature has been scientifically studied, and foods may actually be classified according to their satiety values, as well as their protein and calorie values. When the stomach and upper intestines contain food, and when normal muscular and secretory activities are at work, a feeling of satisfaction or satiety is experienced. Mere distension of the stomach is not enough to excite this feeling, and it is not experienced when the stomach is artificially distended. Slow passage through the intestine is as important as slow passage through the stomach, and the two go together, because foods that remain longest in the stomach call for the greatest secretion of hydrochloric acid. Two factors are taken as the measure of satiety value: (a) the length of time the food remains in the stomach, and (b) the amount of gastric juice stimulated by the food. The accompanying tables are based on observations made in dogs by means of duodenal fistula.

TABLE 1.		Amount of Secretion.	
Food.	Hours.	Meat, 100 grams.	Cal.
Meat, 200 grams.	31-41	200 grams.	516
1 lb. of beef.	31	1000 ml. 500 ccm.	91
1 lb. of mutton.	31	200 ccm.	215
1 lb. of fish.	31	50 ccm.	151
1 lb. of eggs.	21	50 ccm.	151
1 lb. of bread.	2-4	100 grams.	147
1 lb. of butter.	2-4	100 grams.	224
1 lb. of oil.	2-4	100 grams.	225
1 lb. of sugar.	2-4	100 grams.	225
1 lb. of starch.	2-4	100 grams.	225
1 lb. of cellulose.	2-4	100 grams.	225
1 lb. of lignin.	2-4	100 grams.	225
1 lb. of silica.	2-4	100 grams.	225
1 lb. of iron.	2-4	100 grams.	225
1 lb. of copper.	2-4	100 grams.	225
1 lb. of zinc.	2-4	100 grams.	225
1 lb. of magnesium.	2-4	100 grams.	225
1 lb. of potassium.	2-4	100 grams.	225
1 lb. of sodium.	2-4	100 grams.	225
1 lb. of calcium.	2-4	100 grams.	225
1 lb. of phosphorus.	2-4	100 grams.	225
1 lb. of chlorine.	2-4	100 grams.	225
1 lb. of fluorine.	2-4	100 grams.	225
1 lb. of iodine.	2-4	100 grams.	225
1 lb. of bromine.	2-4	100 grams.	225
1 lb. of selenium.	2-4	100 grams.	225
1 lb. of tellurium.	2-4	100 grams.	225
1 lb. of molybdenum.	2-4	100 grams.	225
1 lb. of vanadium.	2-4	100 grams.	225
1 lb. of niobium.	2-4	100 grams.	225
1 lb. of tantalum.	2-4	100 grams.	225
1 lb. of tin.	2-4	100 grams.	225
1 lb. of lead.	2-4	100 grams.	225
1 lb. of bismuth.	2-4	100 grams.	225
1 lb. of antimony.	2-4	100 grams.	225
1 lb. of arsenic.	2-4	100 grams.	225
1 lb. of phosphorus.	2-4	100 grams.	225
1 lb. of sulfur.	2-4	100 grams.	225
1 lb. of carbon.	2-4	100 grams.	225
1 lb. of hydrogen.	2-4	100 grams.	225
1 lb. of oxygen.	2-4	100 grams.	225
1 lb. of nitrogen.	2-4	100 grams.	225
1 lb. of fluorine.	2-4	100 grams.	225
1 lb. of chlorine.	2-4	100 grams.	225
1 lb. of bromine.	2-4	100 grams.	225
1 lb. of iodine.	2-4	100 grams.	225
1 lb. of selenium.	2-4	100 grams.	225
1 lb. of tellurium.	2-4	100 grams.	225
1 lb. of molybdenum.	2-4	100 grams.	225
1 lb. of vanadium.	2-4	100 grams.	225
1 lb. of niobium.	2-4	100 grams.	225
1 lb. of tantalum.	2-4	100 grams.	225
1 lb. of tin.	2-4	100 grams.	225
1 lb. of lead.	2-4	100 grams.	225
1 lb. of bismuth.	2-4	100 grams.	225
1 lb. of antimony.	2-4	100 grams.	225
1 lb. of arsenic.	2-4	100 grams.	225
1 lb. of phosphorus.	2-4	100 grams.	225
1 lb. of sulfur.	2-4	100 grams.	225
1 lb. of carbon.	2-4	100 grams.	225
1 lb. of hydrogen.	2-4	100 grams.	225
1 lb. of oxygen.	2-4	100 grams.	225
1 lb. of nitrogen.	2-4	100 grams.	225

It will be seen that the amount of secretion is not always directly proportional to the amount of a food eaten. It is in the case of meat, but not in the case of bread, potatoes, or butter. So that the great importance of meat lies not only in its value as building and repair material and as fuel, but also in its ability to stimulate the stomach to great physiological activity. Meat and milk stand high, so do eggs, provided they are cooked sufficiently: cooked eggs are not only more easily digested than raw, but they have a greater satiety value. Bread and potatoes rank low if eaten by themselves, but when combined with either meat or fat (as in bread-and-butter) their satiety value is enhanced. Green vegetables, either alone or in combination with meat, have little satiety value. Sugar adds to satiety value in a marked degree. A meal containing something sweet remains longest in the stomach, and thus has the greatest satiety value. Coarse, indigestible foods, roughage in general, not only have no satiety value—they pass rapidly through the stomach—but they lead to subnormal digestion, and, therefore, to a poorer utilization of the contained protein. The popular laxatives, liquid paraffin and agar-agar, however beneficial they may be from a medicinal standpoint, retard digestion and carry away with them a certain amount of nutritive material. The amount of nutriment wasted may not be of great moment, because the majority of people in this country are not driven to support life on a minimal diet. Roughage is responsible in some people, however, for a good deal of vague abdominal discomfort, and even pain, so that appendicitis and colitis may be diagnosed. The discomfort disappears when the roughage is stopped.

Quantitative Requirements

Apart from the biological and the satiety value, the actual quantity of protein that is requisite must be considered. The earlier physiologists, Voit and Atwater, who studied this protein problem, placed the proper intake for an average person at 118 and 120 grams respectively. Then Chittenden introduced the vogue of protein restriction, basing his observations on young, healthy, and enthusiastic young men who, during a brief period of their lives, suffered no harm on 40 to 50 grams daily. Chittenden's experiments have been most damagingly criticized by later workers, who have carried out extensive observations on animals, and by the world-wide involuntary experiences of the war. The conclusions of the Royal Society's Food Committee may be accepted as being of far greater weight than Chittenden's. The committee laid down that 100 grams daily was the average requirement for physical and mental activity and for fertility, 50 grams of which should be "first-class" protein. High protein diets have been shown to have no harmful effects. Stefansson, the Arctic explorer, attributes the vigour and longevity of the Eskimos to the fact that their food is mostly meat, while he himself, when living for long periods among them and sharing their diet, enjoyed the highest degree of physical and mental well-being. Thomas, who studied the exclusively carnivorous Eskimos of Labrador in the MacMillan expedition of 1926, came to the conclusion that their diet did not predispose them to renal or vascular disease.

A liberal protein intake has many advantages. A minimal intake may suffice for repairs and fuelling, but protein beyond those requirements exerts a specific dynamic action which has a stimulating effect upon vigour and general physiological efficiency; it gives, in the words of McFester, "a boost to metabolism," a stimulus which contributes in no small degree to the vigour and virility of the individual and to the stamina of the race. We may get along for a time at least on a minimal protein

intake, but a more generous intake ensures prompt decay and decay, and carries with it a liberal factor of safety.

ENERGY VALUE OF FOODS

For body growth and repair, food is required for the liberation of energy; the energy thus set free appears in the form of heat, mechanical work, and the activity of all the organs and structure of the body. Even the building up of the protein molecule so that it may be used for growth or repair demands the expenditure of energy. The energy contained in any foodstuff can be determined by the measurement of the heat which it yields on combustion in a calorimeter. It is expressed in calories or units of heat, one calorie being the amount of heat necessary to raise one kilogram of pure water from 15° C. to 16° C. For chemical purposes the following values are accepted: 1 gram of protein yields four calories, 1 gram of carbohydrate four calories, 1 gram of fat nine calories. The average working adult requires a diet containing some 3,400 calories, a female about 2,840. For children the requirements are naturally less, but relatively to their weight and body surface their needs are higher than those of adults. A rough rule is that a boy of 14 requires the same calories as his father, and a girl of 14 the same as her mother. But the athletic schoolboy requires as much as 5,000 calories.

Proteins, carbohydrates, and fats can all supply the necessary heat and energy. But to utilize proteins for this purpose is, as a rule, economically wasteful; some part of the nitrogen of the protein is excreted by the kidney, proteins have greater specific dynamic action than carbohydrates and fats—that is, they speed up the metabolic processes of the body—and, finally, in this country, protein foods are the most expensive.

Carbohydrates—These are the most rapidly utilized of all food materials. They are the cheapest, and they reduce protein metabolism; they are "protein spacers." If carbohydrate is added to the diet the amount of meat required will be reduced. The most effective "protein-sparing" diet is a mixture of carbohydrates and fats in which at least half the energy is provided by the former. Wheat is the most economical foodstuff, because of its richness in carbohydrate and protein, the facility with which it can be stored and transported, and the ease with which it is prepared for table. But wheat reaches us in the form of flour—that is, when it is lacking in mineral and vitamin content, and its proteins are of low biological value. We eat it, therefore, chiefly for its carbohydrate content, which is at its highest in bread made of the finest white flour; economically the English are justified in their determination to eat white bread. Other grains are eaten, rice, barley, maize, and oatmeal; their carbohydrate content is practically the same, but their palatability is considerably less. Breakfast cereals are very popular, but thoroughly wasteful and unnecessary. Many of them require cooking, and all of them are more valuable for the milk, cream, and sugar with which they are covered. Their own nutritive value is simply that of the grain from which they are prepared, and very often the extra price paid is merely to cover the cost of diminishing their food value by extracting some nutrient, which is sold in another market. Oatmeal or porridge is a food from which a relatively small proportion of its carbohydrate content can be assimilated. Sugar and sugary foods are valuable in so far as they are converted into glucose. Sugar offers a concentrated form the most readily available carbohydrate, and it possesses a high satiety value. Unfortunately it has also undesirable effects; it is easily eaten to excess, when it promotes obesity, it is a concentrated form of raw material for bacteria, and it is slow to leave the stomach, and it sets up fermentation; and it may be the

cause of a reduction in the consumption of other foodstuffs and lead to dietary deficiencies.

Fats—These have an important place in the diet. They yield twice as many calories as the equivalent quantity of carbohydrate or protein; without fats it is not easy to frame diets of the necessary caloric value. Fatty foods are believed to be indigestible, but much of this is on their nature. Fats which melt at the temperature of the body are most easily assimilated, while those with a higher melting point are poorly utilized. In some people an excessive amount of fat will cause indigestive disturbances, and fat unabsorbed by a syndrome of disease will give rise to ketosis and acidosis. Fatty foods in suitable amount will, as we have seen, lead to retardation of the emptying time of the stomach, and this adds to the sense of comfort and satisfaction. Butter and cream present the most palatable and assimilable form of fat. Fats are expensive, but indispensable; not only do they provide a high caloric yield in compact form, but they are the chief source of certain of the vitamins—namely, vitamins A and D.

Vitamins—An adequate diet must contain all the vitamins, although only minute quantities may be necessary. The average daily diet of adults in this country will contain all the sources of vitamins. For practical purposes a sufficiency of vitamin A and D is obtained from fats. For vitamin B we need not look to the germ of wheat as indispensable; it is found abundantly in yolk of egg, in milk, in the leafy part of green vegetables, and in liver and kidney. It is not destroyed by the heat of ordinary cooking processes. P.P., or B₁₂, is found in similar foodstuffs, and is even more resistant to heat. Vitamin C—the anti-scurvy vitamin—is obtained from fresh fruit and vegetables, and from milk, provided the cow is not fed on oil-cake, but on fresh pasture or ensilage. Vitamin E is found in nearly all our ordinary foodstuffs. For children it may sometimes be necessary to supplement the diet with artificially prepared vitamins, but for adults it will be far better for the home wife to take the advice of the British Medical Association Committee on Nutrition, and "spend money on food whole, some vitamin-containing foodstuffs, than to buy costly preparations of the concentrated vitamin-containing products."

Practical consideration of how to lay out a home-keeping allowance may be interesting. I have prepared a table showing the number of calories which can be bought with a shilling spent on different articles of food. It must be remembered that the purchases must include 100 grams of protein—fifty grams being "first class"—a sufficiency of fat, and the fresh fruit and vegetables necessary to furnish vitamins and cellulose to give bulk to the faeces; some red meat is required for the sake of its iron. The fat must be balanced by the glucose in the protein and carbohydrate in the proportion of $F = 2C + 1P$ at least, otherwise acidosis and ketosis may result. One shilling will buy:

	In Grams			Calories
	Protein	Fat	Carbohydrate	
2 lb. beef	70	0	0	112
2 lb. mutton	17	17	17	170
2 lb. chicken	12	12	2	120
2 lb. turkey	—	—	—	170
1 lb. beef	35	—	170	170
2 lb. mutton	37	—	170	170

I conclude with an analysis of a day's meals, not perhaps such meals as we should take every day, but most of us can probably recall days when we have indulged to an equal extent.

BREAKFAST.	Protein (grams)	Fat (grams)	Carbo- hydrate (grams)
Tea or coffee	—	—	—
Milk, 5 oz.	5	5	7.5

Cream, 1 oz.	1	6	1
Orange, one	15	0.25	25
Total calories, 1,327.55.			

BEVERAGES:	Calories
Martini cocktail	170
One glass sherry	81
Two glasses champagne	210
Two glasses port	170
	664

Note.—664 cal. does not represent the extra energy required in a dinner when carrying a ten stone for two hours.

If you think I have been too generous in catering for you, let me recall Brillat Savarin's wise reflection: "It is one of the privileges of the human race to eat without being hungry and to drink without being thirsty; beasts have not this privilege, for it arises from reflecting on the pleasures of the table and the desire to prolong their duration."

FOOD VALUES

THE BRITISH MEDICAL JOURNAL, JAN. 6, 1934, p. 4

THE "ACUTE EAR" IN GENERAL PRACTICE*

BY

DOUGLAS GUTHRIE, M.D., F.R.C.S.

SURGEON TO THE EAR AND THROAT DEPARTMENT, ROYAL HOSPITAL FOR SICK CHILDREN, EDINBURGH

For years we have been accustomed to speak of the "acute abdomen," an expression which must recall to the mind of every practitioner recollections of the anxiety and heavy responsibility entailed in the conduct of any case of this nature. Certain emergencies connected with the ear are often as serious as those of the abdomen, and it would appear as though the more serious varieties of "acute ear" had been much in evidence during the past few months. Whether this is the result of a warm summer and consequent popularity of swimming pools it is difficult to say. Certainly the percentage of severe ear infections has recently been greater, and in consequence the mortality of the "acute ear" higher. Any little contribution to our knowledge of the subject must therefore be of value, and must assist us to mitigate the fear which the word "mastoid" at present produces in the mind of the average layman.

CAUSES AND CLINICAL COURSE OF ACUTE MIDDLE-EAR SUPPURATION

Acute suppurative otitis is a disease of extreme frequency, especially in childhood. In the majority of cases the ear trouble is preceded by an ordinary head cold or tonsillitis, the infection passing from the nasopharynx to the tympanum by way of the Eustachian tube. It is a common complication of measles, and is also a common accompaniment of scarlet fever. The most frequent cause is a cold, the result of chill, and the organism most often found is the streptococcus. Infection by way of the external auditory meatus is relatively rare, and is usually the result of an accident, such as the penetration of a foreign body or a rupture of the membrane from an explosion or blow on the ear.

The following brief account of a typical case of acute otitis will illustrate the symptomatology.

A boy, aged 9, who had had a cold for a week, complained of sudden pain in one ear. This passed off in about ten minutes but returned a few hours later, and continued to return at brief intervals. When I saw him the tympanic membrane was of deep red colour and slightly bulging near the centre. On incising the membrane there was a gush of thin sero-pus, and pain was at once relieved. The discharge was profuse for four days, and then gradually diminished. As usually happens, the deafness was the last symptom to disappear.

Pain in the ear is the leading symptom in most cases of acute otitis, and may, indeed, be the only symptom. In such circumstances it is well to remember the common causes of earache. A boil or furuncle in the meatus may cause earache, deafness, purulent discharge, and rise of temperature and pulse rate, and, if the meatal wall is swollen, diagnosis may only be possible after repeated observation. Other causes of earache are an unerupted wisdom tooth, a carious molar, arthritis of the temporomaxillary joint, tonsillitis, nasal sinus infection, and herpes auris. The mere recital of such causes illustrates the importance of complete examination in every case.

ATYPICAL VARIETIES OF ACUTE OTITIS MEDIA

A. Latent Otitis in Infants—In small children there may be no symptoms pointing to an affection of the ear.

* A B.M.A. Lecture delivered at Kirkcaldy to the Fife Branch of the British Medical Association on October 19th, 1933.

the so-called "latent otitis." The child is obviously ill, the temperature may rise to 100° or more, there may be vomiting or diarrhoea, and in some cases photophobia and head retraction may cause a suspicion of meningitis.

An infant, aged 9 months, was admitted to a medical ward of the Royal Hospital for Sick Children with indefinite symptoms of this nature. The tympanic membranes were not inflamed, but on both sides the light reflex was absent—an important sign. On morning a little mucus escaped. The temperature at once fell to normal and the general condition speedily improved.

Cases of this nature, not at all uncommon, demonstrate the need for otoscopic examination of every sick child.

B. Septicæmic Otitis.—Sometimes, both in child and in adult, although the otitis is apparent, the general toxic symptoms are so severe as to appear out of all proportion to the local ear condition. The infecting organism is the hæmolytic streptococcus, and the patient presents all the symptoms of acute septicæmia.

An officer, aged 45, returning home tired after a day's shooting, was suddenly seized with severe headache, shivering, and nausea. His temperature rose to 104° and he appeared extremely ill. When seen a few hours after the onset of the symptoms the tympanic membrane was convex, devoid of the usual landmarks, and of deep purple hue. On incision there was a gush of seropurulent fluid. Next day he was still very ill and complained of pain in the knee and hip-joints. There was no sign of marked involvement of any intracranial infection. After incision of the tympanic membrane the ear continued to discharge freely for ten days, during which period the temperature gradually fell and the general condition improved.

Early paracentesis is of supreme importance in cases of this nature and will often avert mastoiditis and other serious complications.

OTOSCOPIC APPEARANCES IN ACUTE SUPPURATIVE OTITIS

From what has already been said it will be obvious that the diagnosis of otitis is based upon careful scrutiny of the tympanic membrane. Every practitioner ought to carry an electric otoscope in his bag and use it very frequently. It is a simple and inexpensive instrument, gives a magnified image of the drumhead, and has a single pneumatic attachment, which is often most useful. The early stages of acute otitis cause redness of the upper and posterior part of the tympanic membrane and of the handle of the malleus, and dilated capillaries are often seen, radiating from the centre. Gradually this red and bulging area extends until the entire membrane is involved. In severe and septicæmic cases this may only take a few hours. Unless relieved by paracentesis the drum will rupture, and just before this occurs a minute yellow-purulent spot may be visible. While this is the usual course of events, there are cases of milder severity in which the membrane may appear wrinkled, devoid of normal lines, and covered with minute shining spots as though dusted with powdered glass. Sometimes, instead of the normal redness, the membrane shows a creamy-yellow colour. In my experience this is commoner in young children. In inflamed cases one or two purple follicles or bullæ are visible, not only on the surface of the membrane, but also on the adjacent bony wall.

APPEARANCE OF THE CONCHA

It is well to remember that the normal tympanic membrane in the infant differs from that of the adult. It is fairly horizontal in position, and the plane therefore appears to be almost continuous with that of the superior wall of the meatus. It is oval rather than circular, and the handle of the malleus is not clearly visible. Anterior

and posterior folds extend across the membrane to the chest process of the tragus, appearing like the wings of a bird in flight, while the cone of light, or light reflex, extends downwards to the lower margin. The appearance of the cone of light is one of the earliest and most reliable signs of otitis media in the child. As acute otitis develops the membrane becomes red, and a bulging area appears in the upper and posterior part, diminishing gradually in front, an appearance rather suggestive of an apophyseal or inverted conical. The inflammation continues, the fold of the apophysis extends around the drum rim, until it meets the handle, and the entire drum membrane then appears to bulge, a slight dimple remaining in the centre when it is anchored to the malleus.

HOW AND WHEN TO INCISE THE TYMPANIC MEMBRANE

An abscess of the tympanum must naturally be treated like any other abscess by incision and drainage. In mild cases, and even in the very early stage of more acute cases, pain may be relieved by the use of glycerine containing 5 per cent. pure phenol. The addition of cocaine is of no advantage, as the phenol is itself a good local anaesthetic. The drops must be carefully compounded, otherwise they may burn the meatus. Local application of dry heat is comforting to the patient, and may be continued even after incision of the membrane. A small electric heating apparatus has been devised for this purpose.

As soon as the presence of pus is suspected the drum should be incised. The small operation of paracentesis tympani can scarcely be too frequently performed. It is the simple, safe, and successful method of dealing with acute suppurative otitis. The best form of paracentesis knife is not the spear-pointed type, which makes a mere puncture, but is shaped like a dinner knife and sharpened on both edges. With this instrument a definite incision is made in the posterior part of the membrane, extending into the adjacent upper wall of the meatus. As the inflamed drum is acutely sensitive, a short general anaesthesia with ethyl chloride is essential. A gauze wick soaked in rectified spirit is introduced as a dressing for twenty-four hours. After that time only a pledget of wool is placed loosely in the ear, and renewed at frequent intervals.

ACUTE MASTOIDITIS: SYMPTOMS AND DIAGNOSIS

While the great majority of cases of acute suppurative otitis run an uncomplicated course a careful watch must always be kept for the appearance of mastoiditis. The following is a very useful history of mastoiditis in a child.

A girl, aged 3 years, entered from home on the night of 1st. Next day the ear discharged profusely and the pain abated. A week later the mother noticed a swelling behind the ear, and brought the child to hospital.

A case like this presents little difficulty of diagnosis. The tragus in the young child is so near the surface that pus readily escapes and forms a superficial abscess. This has been found in one-third of our cases at the Royal Hospital for Sick Children. In older children, and in adults, mastoiditis causes a swelling behind the ear, with marked tenderness and sometimes redness. The temperature is a very important guide, and may rise above the normal level. As mastoiditis develops the ear is discharged, most of the discharge is purulent, and it may continue, and may be very profuse. The conditions most frequently met with in mastoiditis are a bulging of the mastoid skin, and a swelling of the lymphatic glands, which lies upon the mastoid process. A tendril may cause marked tenderness and swelling,

with forward development of the auricle. The hearing is good and the tympanic membrane normal in appearance, but when the meatus is so swollen that the membrane is not visible, correct diagnosis may be very difficult. Suppuration of a lymphatic gland behind the ear may accompany impetigo of the scalp and may simulate a mastoid abscess, but otoscopic examination will reveal a normal ear.

An Uncertain Sign

The sign upon which a diagnosis of mastoiditis is usually based is the presence of tenderness over the mastoid area. Tenderness on pressure or on percussion is strong evidence of mastoiditis, but its absence does not signify that mastoiditis may be excluded. Indeed, in many cases of widespread mastoid infection tenderness is *completely absent*: This is noteworthy in cases of septic thrombosis of the lateral sinus. Of 150 cases of mastoiditis treated at the Royal Hospital for Sick Children, four cases were complicated by lateral sinus thrombosis, and in each of those four cases mastoid tenderness was absent. Diagnosis was based upon other signs, such as the characteristic remittent temperature. Moreover, mastoid tenderness is found in the early stage of many cases of simple otitis, and passes off within a day or two.

For example, a nurse, aged 24, suffered from sore throat for a week, then earache for two days, then aural discharge. When seen at this stage she had a temperature of 101°, profuse discharge of thin pus, and tenderness of the entire mastoid process. Two days later the tenderness was gone and the discharge was less. Within ten days the ear had returned to a normal condition.

Early mastoid tenderness, therefore, is of less diagnostic importance than tenderness which appears a week or more after the onset of the otitis.

Unusual Types

The pus from a mastoid abscess may track in various directions. For example, when the cells in the root of the zygoma are infected pus may collect beneath the temporal muscle and give rise to swelling and tenderness above and in front of the ear—the so-called zygomatic mastoiditis. Again, the pus may escape through the inner aspect of the mastoid process and find its way below the sterno-mastoid muscle into the tissues of the neck, causing a tender swelling behind the angle of the jaw and below the mastoid tip; this is known by the un-descriptive title of "Berold's mastoiditis."

EARLY SIGNS OF INTRACRANIAL INFECTION

The intracranial complications of suppurative otitis media are fortunately rare. The symptoms are often so indefinite that the real cause is apt to be overlooked.

A little girl of 9 years was suddenly seized with headache, vomiting, and fever. The case was treated as influenza for a week and the vomiting abated, but the headache continued, and just before admission to hospital there was a rigor and the temperature rose to 103°. There was no discharge from the ear and no mastoid tenderness. On inquiry, however, it was ascertained that there had been a slight discharge from the right ear just before the illness, and on inspection a small perforation of the membrane was found. Thrombosis of the lateral sinus was suspected, and this was verified by operation. A thickened pus in the antrum and cells and a gangrenous and collapsed sinus wall bathed in thin blood-stained fluid.

This illustrates the difficulty of diagnosis in septic cases thrombosis. It may readily be mistaken for influenza, endocarditis, typhoid fever, and other febrile diseases.

To quote another recent case:

A youth of 17, who walked to hospital, complained of double vision, swelling behind the left ear, and profuse discharge from the ear, which had lasted for a week. There had been practically no pain, but a paralysis of the external rectus muscle (sixth cranial nerve), the so-called Gradenigo sign, pointed to an infection of the apex of the petrous part of a temporal bone containing numerous air cells.

This type of mastoiditis, known as apicitis or petrositis, has recently attracted the attention of otologists. It is a serious condition, and may end in meningitis.

As a final instance of an "acute ear" with complications I will quote the following case:

I had operated on a boy, aged 14 years, for tuberculous otitis during the first year of his life. A radical mastoid operation had been performed, and as sometimes happens the cavity had filled in course of time with that flaky, shining material known as cholesteatoma. This had produced a fistula of the external semicircular canal, and when the boy came to hospital for the second time he was suffering from giddiness, vomiting, and nystagmus directed to the opposite side. There was no fever and no rise of pulse rate. The mastoid region was tender, and pressure behind the ear immediately increased the vertigo. At operation the wound was reopened, the cholesteatoma removed, and the fistula demonstrated. All the symptoms disappeared and the boy rapidly recovered.

WHEN TO OPERATE

The treatment of mastoiditis is essentially surgical, but this does not mean that every suspected case should undergo operation forthwith. As already mentioned, mastoid tenderness is present in many cases of acute otitis, and although this may indicate a mild degree of mastoiditis, it may pass off within a few days under conservative treatment. Cases of this nature one must watch very carefully, noting any increase of tenderness or appearance of oedema, or swelling of the upper and posterior wall of meatus, and observing the general condition of the patient—also his temperature and pulse rate—so that operation may not be unduly delayed. Mastoiditis is not in itself a fatal disease. By operating too early, before allowing time for the patient's resistance to take a part in combating the infection, we may actually precipitate a spread of infection to the blood stream (septicaemia) or to the meninges (meningitis). Too long delay is of course equally unwise. The decision to operate must necessarily vary according to the experience of the operator, and the essential fact which the practitioner should grasp is that every doubtful case should at once be brought under the skilled supervision of an otologist. As that course is not always possible, it is sound practice to operate when in doubt.

Having decided that operation is necessary, we must see to it that a thorough operation is performed. Although some cases of mastoiditis with a superficial abscess recover after simple incision, this is not good surgery, and one need only glance at a section through a pneumatic type of temporal bone to realize that all the suppurating air cells should be systematically opened and drained. When Neumann said that "the simple mastoid operation should be as radical as possible, and the radical operation as simple as possible," he meant that in acute mastoiditis a wide and free drainage was essential (having, of course, an intact tympanum) and that in chronic suppurative otitis the structures concerned in hearing should be preserved as far as possible.

[Mr. Guthrie then showed lantern slides illustrating the surgical anatomy of the temporal bone in the adult and in the child, the technique of otoscopy, the clinical features of mastoiditis, and the steps of the Schwartze operation.]

OVULATION AND MENSTRUATION

BY

WILFRED SHAW, M.D., F.R.C.S., F.R.C.O.G.

ASSISTANT PHYSICIAN, ROYAL FREE HOSPITAL, 47, LINCOLN SQUARE, LONDON, W.1.

Relatively few contributions have been made in recent years to the study of the time relations between ovulation and menstruation in the human female. The work of Robert Meyer,¹ Robert Meyer and Ruge,² Schröder,³ and Kovacs⁴ indicated that ovulation was restricted to the intermenstrual phase. In 1925 I⁵ published some observations of my own which furnished additional evidence in support of this view. Since then publications have attacked the problem indirectly, some have supported the view expressed above, others have opposed it. As a result much confusion exists at the present time, and I have thought that an examination of the material collected since 1925 might help to clear up some of the difficulties which have arisen. There has perhaps been a tendency in recent years to attach too much importance to formulating a parallel between the sex cycles of man and the lower animals. When the results of gynaecologists have not agreed with the interpretations of animal workers, experimentalists have sometimes been apt to denigrate the gynaecological point of view with scant respect. An attempt will be made below to restrict the observations and interpretations to the human material, and not to be unduly influenced by the results of animal work. Homologies and such like excursions can conveniently be left to the biologists.

The normal menstrual cycle is regarded as one of twenty-eight days, the first day of the period of bleeding is taken as the first day of the cycle. The phases of the menstrual cycle are referred to in terms of the particular day after the first day of the last period.

Schröder has pointed out that the following methods are available to investigate the time relations:

1. The inspection of ovaries during abdominal operation. Friedländer originally employed this method and gave a wide variation between the tenth and fourteenth day of the cycle. The method is not capable of great precision, and having examined ovaries carefully for ten years I am still unable to distinguish between immature follicles and recently ruptured follicles by naked-eye examination alone.

2. The determination of the point of *Mittelschmerz*. This method is unreliable, and personally I do not believe that *Mittelschmerz* is caused in all cases by the rupture of a follicle.

3. One of the most trustworthy methods is the determination by histological means of a recently ruptured follicle in a carefully dated material. Post-mortem material is of little if any value, partly because it is rarely accurately dated, and partly because its histology is often doubtful.

4. This method is indirect and is based upon the assumption that the secretory phase of the endometrium develops progressively after ovulation. The histological appearance of the endometrium during the secretory phase is suggestive. If it can be demonstrated that in the endometrium it is assumed that ovulation has taken place previously.

5. Similarly, however, can be obtained from the detritus, produced by the growth of the endometrium, as the histological observations of the menstrual cycle.

6. The most accurate of all methods is the determination of the ovulation time by direct observation. After a long period of doubt it is now generally accepted that ovulation is restricted to the intermenstrual phase of the cycle.

Schröder, who has a long list of carefully dated material from ovaries, also states that the point of ovulation is constant during the menstrual cycle. I have little doubt in my own mind, except perhaps for very rare exceptions. At the other extreme is the case of Kovacs, who has shown that ovulation depends on a constant duration of the cycle.

IMPORTANCE OF ACCURATE DATING MATERIAL

Schröder has pointed out that many of the discrepancies in the published work on the determination of the time of ovulation depend upon the accuracy of material which is not accurately dated. It should be remembered that Krieger and Fehring have shown that a menstrual cycle of twenty-eight days is present only in 60 per cent. of women. Similar figures are given by Hagedorn (55 per cent.) and Weinstein (58 per cent.). It is clear, therefore, that a material not taken in comparing the time of ovulation in a twenty-eight-day cycle with the results found in a cycle of twenty-one days. In a paper on uterine cancer, published in 1929,⁶ I showed that when the cycle is a reduced ovulation occurs much earlier than the accepted fourteenth day. Similar observations have been made by Quinn, who demonstrated that the constant factor for all menstrual cycles is the time between ovulation and the succeeding period. In the present contribution I have restricted the material to cases with twenty-eight day cycles.

MATERIAL IN PRESENT INVESTIGATION

The specimens have been obtained by operation for various gynaecological conditions as indicated in my hyperplasia. In all cases data have been available as to (a) the first day of the last menstrual period, (b) the date of the operation, and (c) the normal cycle for the patient concerned. I have taken great pains to collect accurate data, and have rejected all cases in which the details were not precise. It is frequently found that patients are unable to remember exactly when their last period began. It is also remarkable how many women have cycles departing by a day or two from a strict twenty-eight day cycle, who maintain that their cycle is regular for twenty-eight days, until they are closely questioned. I have observed thirty-six cases in which the ovaries have been examined from patients with accurate menstrual histories. In addition I have observed forty-nine cases in which the uterus alone was removed. In twenty-one of the patients in whom the ovaries were examined the uterus was also removed, but for other reasons. The material therefore consists of thirty-six cases in which the cyclical changes in the ovaries could be examined, and seventy in which the cyclical variations of the endometrium could be studied.

OVARIAN GROUP

Thirty-six cases belong to this group. The specimens are dated as follows:

Date of operation	No. of cases	Interval between operation and last menstrual period
1	1	Interval 14 days
2	1	" " "
3	1	" " "
4	1	" " "

TIME OF OVULATION

I will describe first the ovarian material. There were thirty-six cases in all. Six specimens of a recently ruptured follicle were secured; the classical signs of a recent rupture were found in all; there was extreme haemorrhage in the theca interna layer, and the granulosa cells were both proliferating and undergoing hypertrophy. The corpus luteum convolutions had not as yet formed. Four specimens were obtained on the thirteenth day and two on the fifteenth day of the cycle. These six specimens of recently ruptured follicle support the view that ovulation had taken place some time about the fourteenth day of the menstrual cycle. It is impossible to state how rapidly the ruptured follicle proliferates, and consequently one could not deduce exactly when ovulation had taken place. There are some grounds for believing that growth is extremely rapid, for the proliferation of a young corpus luteum about the seventeenth day of the cycle can be traced more accurately when it is found that after the twentieth day of the cycle the corpus luteum is fully developed. If, therefore, it takes only a few days for the corpus luteum to attain full maturity, it is reasonable to assume that the growth of a recently ruptured follicle is very rapid. For these reasons I believe that the six specimens of recently ruptured follicle were obtained soon after ovulation, and the demonstration of these offers direct evidence that ovulation is restricted to about the fourteenth day of the cycle.

The series examined does much more than this. The other cases, though not affording direct proof, indirectly favour this view. For example, in all specimens after the thirteenth day, thirty cases in all, there was none in which the ovaries did not contain either a recently ruptured follicle, a proliferating corpus luteum, or a mature corpus luteum. The later in the cycle that the specimen was removed the more mature was the corpus luteum. Proliferating corpora lutea were found, particularly about the seventeenth day. Lastly, in specimens observed in the early part of the cycle no recently ruptured follicles were found, and the corpora lutea detected in the ovaries were retrogressing. I wish to emphasize that the series is important, not merely because of the six specimens of recently ruptured follicle, but because the others circumstantially endorse the opinion that ovulation is restricted to about the fourteenth day.

IS TIME OF OVULATION CONSTANT?

The series of specimens show that ovulation is restricted to about the fourteenth day of the menstrual cycle. On the other hand the samples of recently ruptured follicle indicate quite clearly that there is a little variation in the ovulation time. For example, one of the two recently ruptured follicles removed on the fifteenth day was younger than any of those of the thirteenth day. Similarly, in the specimens of the thirteenth day there were different degrees of development. This implies that ovulation cannot be regarded as occurring always at a fixed time with all regularly menstruating women, and that there is a variation of at least two days in the ovulation time. Personally, I have no objection to postulating a parallel to the variations which Hartmann¹ has found in the ovulation times of his colony of macaque monkeys. It is probable, however, that a departure of more than two days from the fourteenth day of the cycle is hardly ever, if ever, seen in the human subject. A further point should be borne in mind. However accurate the history, there is always a possibility of a little margin of error in the determination of the ovulation time. For example, a patient may start menstruating late one evening and the operation, which leads to the demonstration of a recently ruptured follicle, be performed early one morning. In such a case there is a margin of error of twelve hours in timing the specimen, and with two extreme cases of this kind a margin of twenty-four hours can be expected.

EVIDENCE AGAINST THE ACCEPTED TEACHING

Well-authenticated cases are on record in which no corpus luteum has been found post mortem in the ovaries of women who have been menstruating regularly. Examples are given by Teacher² and by Corner.³ It is not uncommon for patients who are desperately ill to cease menstruating shortly before death, and amenorrhoea of this kind is not infrequent. It is probably very exceptional to find no corpora lutea in the ovaries of women who have menstruated regularly, and such cases should be looked upon as pathological. The series which I have just described illustrates that regular ovulation can be demonstrated in the ovaries of women with normal menstrual cycles.

Embryologists maintain that ovulation can be "provoked" by coitus, for it is sometimes difficult to admit that an early human ovum can attain its size in the short time available if ovulation is limited to about the fourteenth day of the cycle. Similarly, cases are recorded in the German literature in which pregnancy has followed a single coitus in the post-menstrual phase. My own view of these cases is that they can be explained in ways other than by assuming an alteration in the time of ovulation. If ovulation can be "provoked" by coitus one would have expected to find evidence of aberrant ovulation in such a series of specimens as I have described above. It is clearly impossible to deny that ovulation can be "provoked" by coitus; all that can be said is that, if it does occur, it is very exceptional.

Animal workers have sometimes been inclined to discredit the observations of gynaecologists on the time relations between ovulation and menstruation, in view of Corner's work on macaque monkeys. Corner has observed that macaque monkeys may develop cyclical uterine haemorrhage without ovulating, and it has even been suggested that menstruation in women may be comparable to this form of uterine bleeding. I shall show later, when dealing with specimens of the endometrium, that menstruation consists essentially of the degeneration and disintegration of a premenstrual endometrium. I have always admitted the possibility of uterine bleeding occurring independently of ovulation, but such cases should be looked upon as pathological. Cases of metropathia haemorrhagica afford the best example of this type of uterine bleeding. As I have already pointed out, I have always found evidence in my material that cyclical uterine bleeding in healthy women is accompanied by ovulation, and in consequence believe that ovulation should be regarded as forming an essential part of the sex cycle of women.

THE CYCLICAL CHANGES IN THE ENDOMETRIUM

Seventy specimens of the endometrium were examined. The material consisted of sections through the thickness of the uterus, and included both endometrium and myometrium. The seventy specimens were accurately dated as follows:

Day	No. of Specimens	Day	No. of Specimens
1	4	15	1
2	7	16	1
3	7	17	7
4	1	18	2
5	2	19	4
6	1	20	2
7	2	21	3
10	4	22	1
11	1	23	1
12	1	24	3
13	2	25	3

SUMMARY

1. I have attempted to picture the relation between ovulation and menstruation in women who menstruate regularly with a normal rhythm. I have shown in other publications that irregular bleeding is characterized by departures from the normal relations.

2. The time relations of ovulation and menstruation have been reinvestigated with the use of the method of identifying recently ruptured follicles in the ovaries of women who give reliable histories.

3. It has been shown that ovulation is restricted to about the fourteenth day of the cycle.

4. There is some variation in the time of ovulation, but the variation is probably not more than two days from the fourteenth day.

5. A study of the condition of corpora lutea at other stages of the cycle confirms this view.

6. Indirect proof as to the time of ovulation can also be obtained by an examination of specimens of the endometrium of the uterus. It has been shown that the secretory phase of the endometrium develops after the fourteenth day of the cycle. The specific features of the secretory phase are never seen before the fourteenth day.

7. Seventeen specimens of the menstruating endometrium have been examined. In all cases there was evidence of previous premenstrual hypertrophy. In the material examined no parallel was found to the anovular cyclical bleeding of the macaque monkey.

A CONTRIBUTION TO THE GENETIC STUDY
OF MENTAL DEFICIENCY

BY

L. S. PENROSE, M.D.

RESEARCH MEDICAL OFFICER, ROYAL EASTERN COUNTIES'
INSTITUTION, COLCHESTER

The following family history is unusual from several points of view. It records the results of the union of a brother and sister. The brother is insane and of low mentality, and the sister is certified feeble-minded. Three children were born to the sister, and the brother was almost certainly their father. The mental condition of these children is a matter of great interest, both from the genetic and from the sociological points of view. Details of the members of this incestuous family group are now given.

GENERAL FAMILY HISTORY

The brother and sister were fifth born and eighth born, respectively, in a family of eight children. Their parents were ordinary, working-class people, and both lived to be over 80. One of the mother's sisters is said to have been subject to epilepsy, and a great-great-nephew, who is also epileptic, is certified feeble-minded. Apart from these instances we have little evidence in the family of what could be termed neuropathic traits, although a sister of the incestuous couple, the seventh born in the family, is reported as mentally dull. This sister married a first cousin on her father and on the mother's side, and has eleven children, all of whom are said to be capable and intelligent.

THE BROTHER

He is now aged 54, and in a mental hospital suffering from general paralysis. He has been given a course of malaria treatment, and, while the physical condition remains fairly good, he shows a severe dementia. No definite measure of his mental capacity has been obtained, but his general intelligence is reported to have appeared subnormal before the onset of dementia. In view of the average level of intelligence among his sisters, it is improbable that his mentality was high. Unfortunately it has been impossible to trace his record at the Roman Catholic school where he was educated.

After leaving school he was employed as a stable boy, and he later drove a cab. Then he joined the Army, from which he deserted in South Africa. He worked his passage to England, and shortly afterwards began to live with the sister who was eight years his junior. The man earned his living as a general labourer at the gasworks, and the woman did some occasional charring. The couple remained together as man and wife for fifteen years, and, according to contemporary accounts, they were on very affectionate terms. They seemed to be happy and were fond of their three children, who were born during this period. The first, a male child, died at the age of 2½ years; there is no evidence that this child was abnormal. A year or two after the death of this child another boy was born, who is still alive. Some ten years after this, relatives of the couple discovered that the woman was again pregnant. An anonymous letter was sent to the police suggesting that the state of affairs required investigation. Two officers in plain clothes called at the flat where the couple and their son were living, only to find that they had absconded, leaving their belongings behind. Two years later they were located, living under an assumed name, in a neighbouring town; another boy had, in the meantime, been born. The man and woman were arrested and, at the Petty Sessions, were committed for trial to the Assizes. They were not legally represented. During the intervening period the woman was examined by the medical authorities, and it was decided that she was mentally defective. The man was apparently not examined from this point of view. He was convicted under the Punishment of Incest Act, and sentenced to sixteen months' imprisonment. A year after his release from prison he was certified insane.

THE SISTER

She is aged 46 and certified mentally defective. She is thin, and appears to have been poorly nourished; she is quiet and reserved in her behaviour, and speaks clearly and connectedly. The Wassermann reaction is negative. She is occasionally liable to fits of temper, but is a diligent worker in the laundry of the institution where she is now cared for.

Although she had been educated, like her brother, at a Roman Catholic school, on admission to this institution (by an order made in court) she could not tell the number of feet in a yard, and stated that Scotland was the capital of England. She has been tested since, by standardized tests, with the following results: Binet tests (Stanford revision), 8 years 10 months; Porteus maze test (Vineland revision), 8 years; Healy pictorial completion test, No. 1, 7 years. Her mental ratio, or intelligence quotient, is therefore roughly from 50 to 60 per cent. (according to whether we take 16 years or 14 years to be the maximum divisor).

SURVIVING CHILDREN

There are two surviving children, both male, aged 17 and 7 respectively. The elder is physically rather small, but healthy and active. He is quick-witted, and appears very sensible in conversation; his appearance is not very

The continuous introduction of saline, or saline and glucose, by the intravenous route is now possible. The disappointing report that the saline has been returned when it is most required—a report only too frequent when proctoclysis is employed—does not enter the picture here. A slow and continuous intravenous flow approaches the ideal; for we know exactly how much fluid the patient is receiving. The fluid can be given continuously over a period of three to five days, or even longer, and the rate of flow and the amount of fluid to be given can be regulated with mathematical precision. There can be no doubt that the continuous introduction of fluids intravenously promises to become a form of therapeutics capable of tremendous application.

Like these other life-saving procedures—Fowler's position and proctoclysis—the continuous administration of saline intravenously hails from America. In 1924 R. Matas¹ advocated a continuous intravenous drip giving 5 per cent. glucose in distilled water into a vein over a period of several days. In 1930 G. A. Hendon² published an excellent communication setting forth the advantages of the method. Later, the writings of J. S. Horsley,³ W. E. Gallie and R. I. Harris,⁴ and F. B. Ramsey⁵ added to our knowledge of the subject.

THE TECHNIQUE DESCRIBED

We will assume that the reader is familiar with the process of tying a cannula into the vein. Emphasis will be placed upon those points which ensure success in continuous administration of intravenous fluid.

FIG. 1.—A vein on the back of the hand, preferably the left, can be used. The cannula may be fixed in position by adhesive in this situation. A Carr's splint is useful to keep the hand at rest.

Choice of the Vein.—In general it is best not to use a large vein; one just a little larger than the cannula is ideal. The veins about the elbow are too large, and the impracticability of keeping the elbow extended and at rest for days rules out this favourable site for intravenous injection. Gallie and Harris prefer to use a vein on the back of the hand (Fig. 1). For obvious reasons it is less irksome for the patient if the cannula is tied into a vein of the lower extremity. A possible disadvantage of employing veins of the lower extremity is that after fluids have been injected into them they are prone to thrombose. However, experience shows that when sodium solutions are employed—and particularly when the concentration is not more than 5 per cent.—the fear of producing thrombosis is largely theoretical. For extremely ill patients who are restless, or who may become so, we prefer to tie the cannula into the saphena or one of its branches, a handbreadth below the knee, or, better still, when it is accessible, the vein just in front

of the internal malleolus. After infiltration with local anaesthesia the vein is conveniently exposed by a transverse incision.

The Cannula.—It is advisable, but not absolutely essential, to have a special gold-plated cannula, of which there are several types available (Fig. 2). The cannula and the wound should be moist with citrate solution at the time of the introduction.

FIG. 2.—A cannula for venoclysis. It is gold-plated to prevent corrosion. There are two lateral holes (A) in addition to the terminal opening. The collar (B) allows the straight portion of the cannula to be tied into the vein snugly. The sloping neck (C) can be bent to any angle suitable for varying depths of subcutaneous fat in individual cases. The perforations in the wings (D) permit anchoring the apparatus to the skin by means of sutures.

Keeping the Limb at Rest.—If a vein on the dorsum of the hand is used a light anterior splint is employed to immobilize the hand and forearm. When the lower extremity is selected a back splint with a foot-piece usually answers the purpose. In a restless patient a Thomas knee splint (Fig. 3) is a very good method of ensuring that the cannula does not become displaced.

FIG. 3.—The apparatus* in use. In very ill patients who are restless, or may become so, this method of fixing the limb minimizes displacement of the cannula.

Bandages.—It is obvious that even a moderately tight bandage proximal to the cannula may obstruct the vein. The nurse should be warned of this possibility when adjusting the splint. If a Thomas splint is used bandages around the limb are unnecessary, which is an advantage.

Avoiding "Reactions."—The whole apparatus can be sterilized by boiling. Especially when it is new, the

* The apparatus is made by the Gumbo-Uriary Manufacturing Company.

have been overlooked if the attention of the radiologist had not been focused for some time on this disease. In the absence of the skull radiopacities, the age of the patient might have led one to omit the x-ray examination of the limbs. It would seem that the investigation for the cause of epilepsy or allied mental and psychical conditions cannot be regarded as complete until a thorough search has been made in the soft tissues for the presence of the calcified cysticercus. It is imperative for the radiologist to be acquainted with the possible appearances of the calcified or early calcifying cysticercus. The figure [reduced to 2/5 linear] shows the various shapes seen in the radiographs of twelve cases in this hospital. Their actual size can be calculated from the millimetre scale reproduced at the right-hand lower corner.

CALCIFICATION OF THE CYSTICERCUS

Calcification of the cysticercus in the brain is rare in our series of cases, and was found in only one other out of twelve. At present radiology can play a part in the diagnosis only when calcium is deposited in the dead parasite—that is, relatively late in the disease. It is to be noted that the presence of calcified cysticerci by no means excludes the presence of living parasites in the same patient. The amount of calcium deposit and the time taken for this depend on various factors not yet fully understood. The radiopacities in the tissues in a case of cysticercosis represent: the calcifying or calcified scolex, the true bladder in which it developed, the remains of the fluid contents of the true bladder, the outer cyst wall provided by the tissues of the host, and the remains of the fluid contents of this outer cyst. The shape depends on the pressure by neighbouring structures.

The scolex, as the solid portion of the bladder-worm, may be expected to receive the heaviest deposit, and this fact is well illustrated in Shape 4 ("oval with spot"), which in the radiograph exactly resembles the excised scolex as with its glistening "milk-spot" on the bladder wall. Cavitation before calcification will explain the appearance of the lines indicated in the various diagrams. Many of the calcified cysticerci show a very definite halo, which is accepted as indicating calcification in the outer cyst wall or in its outside layers.

The skull radiograph is often asked for in a case of epilepsy, but if there is the least reason to suspect cysticercosis it would be much better to devote the radiographic examination to the soft tissues. The routine in such a case at present is: lateral view of the skull, roof of skull, upper arm, femur, thighs, and legs.

DIAGNOSIS

The figure showing the various shapes indicates what the radiologist has to search for in the tissues. The names

are given for easy reference in the viewing of radiographs. There may be countless numbers present, making diagnosis simple, or the search may have to be a minute one for the identification of a single cysticercus in a very early stage of calcification. When this is found, and corresponds to any of the very definite shapes indicated, the diagnosis can be made. Solitary doubtful calcifications can be localized, excised, and, after solution of the calcium salts with weak hydrochloric acid, a search can be made for the

hooklets of the scolex. Radiological examination at six-monthly intervals may be indicated in certain cases.

The advantages of diagnosing the presence of the condition are:

1. For the diagnosis of the actual complaint.
2. For assessing the responsibility of service or employment for the presence of the disease—for example, epilepsy.
3. For assistance in the diagnosis of generalized or localized brain lesions.
4. To prevent operative treatment where the end-result is unlikely to be successful—for example, very heavy infestation.
5. To remove the hereditary stigma of "epilepsy."

I wish to acknowledge the help of Colonel W. P. MacArthur, who is responsible for this investigation, the co-operation of Major H. B. F. Dixon, and the assistance of Captain F. P. M. Anderson in obtaining the clinical notes of the particular case described.

ARTIFICIAL PNEUMOTHORAX IN THREE CASES OF PULMONARY TUBERCULOSIS IN CHILDREN

BY

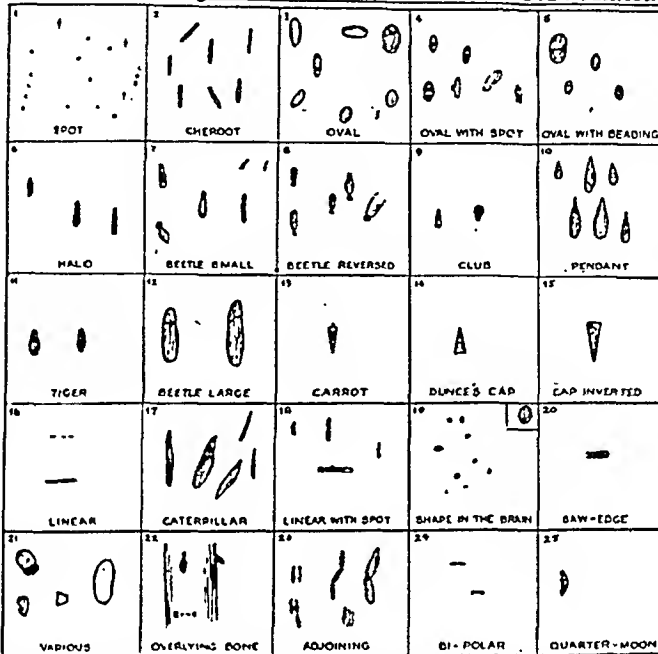

WILLIAM STOBIE, M.D.Ed., M.R.C.P.

HONORARY PHYSICIAN, OSTER PAVILION FOR TUBERCULOSIS, RADCLIFFE INFIRMARY, OXFORD

Pulmonary tuberculosis of the adult type with a positive sputum in children is generally recognized to be uncommon; indeed, before the age of 10 it has been classed as "a medical curiosity." While in the strictest sense this is hardly correct, the disease is unquestionably rare in the first decade of life. The outlook for these patients is grave. One authority² on diseases of children says he has "never seen a case recover in which a definite diagnosis of pulmonary tuberculosis could be made." This experience is particularly unfortunate and not universal. A certain number of the afflicted children do recover, and remain well.

In an endeavour favourably to influence the prognosis, collapse therapy was instituted in the following three patients, who were sent to the Oster Pavilion, Radcliffe Infirmary, by Dr G. C. Williams, medical officer of health for the city of Oxford, to whom I am indebted for their early history.

as to the high efficacy of liver injections in most patients. Several brands of liver extract have been tested; 1 c.cm. has sufficed for several cases—for example, four injections of 1 c.cm. kept a patient in comfort through a ten-day course (daily treatments, breast case). The effect of each injection lasted two days; on the following morning there was nausea or sickness before breakfast. For such slighter cases oral administration might prove satisfactory.

(From the Radiological Department, Middlesex
Hospital)

TREATMENT OF SCABIES

Scabies occasionally appears in a form highly resistant to treatment, and, in spite of vigorous and careful hygienic measures, it may be very difficult to obtain for the patient relief for any reasonable length of time before recurrence of the symptoms.

Mr. M. W., aged 48, an intelligent merchant, consulted me towards the end of January, 1933. He complained of irritation of the skin all over his body for nine months. Latterly the irritation was affecting his face and neck, but not his scalp. It was much worse at night, when he was warmed up in bed. On examination many of the characteristic burrows of scabies were distinctly visible, with a few vesicles and many linear excoriations in parts of his anatomy accessible to his finger-nails. The diagnosis had been confirmed by a consulting dermatologist, and he had undergone repeated treatments with sulphur. He had never been free of irritation for more than a few hours after the treatment, and he was now suffering severely also during the day. I gave him several courses of treatment, using sulphur ointment in varying strengths up to the strength of the B.P. ung. sulphuris, and β -naphthol ointment in strengths of from 2½ to 7½ per cent. There was no improvement which lasted longer than one day. Five months ago I prescribed "mitigal" (dimethyl diphenylene-disulphide), and asked him to rub this into his skin all over the body (scalp excepted) on three consecutive occasions, with the usual precautions with regard to bedclothing and underwear. The total amount of mitigal used was 150 grams. The skin lesions completely disappeared, he became entirely free from irritation, and has remained so since.

I have never before this case failed to record a cure with the proper and intelligent application of sulphur. The chronicity of this complaint over a long period of one and a half years, its failure to react successfully to the usual therapeutic measures, and the complete cure with mitigal justifies my recording of this case.

London, E. 2

SEVERE PENETRATING CHEST WOUND

On August 9th, 1933, a boy of 10, riding his bicycle down a side road, ran into a motor car passing along the main road. His front wheel was so twisted round that the handles of his machine pointed upwards; he was literally impaled on one of these, and had to be lifted off it. The handle made a wound three inches long, just to the inner side of the angle and vertical border of the scapula on the right side. The sixth rib was fractured and the pleural cavity opened, the opening being large enough to admit four fingers.

Under a general anæsthetic the skin edges were excised, four fragments of muscle removed, and the wound well swabbed out with carbolic lotion. The collapsed lung could just be felt with the finger-tips, but did not appear to be torn or bruised; the intercostal membrane and muscles above and below the fractured rib had disappeared, and one had to be satisfied with suturing the remaining parts as firmly as possible over the opening into the pleural cavity, and then closing the skin wound. Rather extensive surgical emphysema developed, but the wound remained clean and dry, and the patient's

* B. & C. Ltd. is the sole British agent for Liver Products Ltd.

temperature after twenty-four hours was always normal morning and evening.

After operation the apex beat was two inches outside the nipple line, but by the fifth day it was in the nipple line, and on this day pleural friction was audible in the right axilla, proving that the lung was expanding well. The patient had no cough and no expectoration, which suggests, I think, that the lung was not injured, but must have collapsed very rapidly out of the way of the bicycle handle when it entered the chest cavity. He was given antitetanic and anti-gas-gangrene serum at the time of the operation; he had been thoroughly tanned by a fortnight's exposure to the sun before the accident, so that his power of resistance to infection was at a high level. At the time of the accident the boy's shirt was torn, but none of it was apparently missing, and nothing was left inside the pleural cavity. As far as one could make out there was no hæmothorax, but the surgical emphysema made it impossible to percuss out any dullness at the right base during the first week after the accident. At the end of a fortnight the wound was healed and the lung was fully expanded, the breath sounds at the base of the right lung being as good as those on the left side.

During two years' experience of chest wounds at casualty clearing stations in the war, I never saw a case with such a large wound do better or cause less anxiety, and I would put this down to the patient's fitness at the time of the accident. I should like to emphasize the great importance of immediate closure of an open chest wound; in this case the wound was closed one and a half hours after the accident.

Swanage.

Reports of Societies

CYSTICERCOSIS AS A CAUSE OF EPILEPSY

At a meeting of the Royal Society of Tropical Medicine and Hygiene at Manson House on December 14th, 1933, with the President, Sir LEONARD ROGERS, in the chair, Colonel W. P. MACARTHUR read a paper on cysticercosis as seen in the British Army, with special reference to the production of epilepsy.

Colonel MacArthur said that, on an average, about one hundred soldiers were discharged from the Service every year on account of epilepsy. After excluding those with an inherent epileptic taint, traumatic lesions, syphilis, and neoplasm, there remained a considerable number of men, coming from sound nervous stock and previously healthy, who developed fits after service abroad. In the past occasional cases of cysticercosis complicated by epilepsy had been diagnosed in the Army, but these had been looked upon rather as isolated curiosities of medicine, and their significance as outcrops of a more generally distributed occult infestation had not been appreciated. More recently his own observations, and the independent work of Colonel R. Priest, R.A.M.C., had revealed the close association of the two maladies, and eighteen months ago the War Office had issued orders that all men who developed fits were to be sent to Millbank, where over twenty cases of cysticercosis had been diagnosed this year. Man was the sole host of *Tænia solium*, and, though normally this parasite passed its cysticercic stage in the pig, given the opportunity cysticerci readily developed in man. The incubation period of the disease was difficult to assess, and prodromal symptoms were generally absent, though occasionally a history of headache, unidentified fever, myalgia, rheumatic pains, and localized oedematous swellings in the muscles was obtained. In the established disease palpable cysts in the subcutaneous or muscular tissues were an outstanding feature, but often they were not demonstrable. A peculiar feature was the manner in which cysts might continue to appear singly or in crops for many years, whilst others, already evident, might suddenly increase in size. Such cysts, generally regarded as of recent origin, contained fluid under tension, and as the lecturer said, he had invariably found the larvae were dead and undergoing degeneration,

Rest in the treatment of heart disease implied mental as well as physical rest; mental strain must always be relieved if in any way possible.

Miss D. W. HALL pointed out that the portal of entry of the haemolytic streptococcus might be through the nasal mucous membrane as well as through the tonsils. Dr. DONIS OBLUM maintained that the treatment of the psychogenic factor which was so prominent in some cases of thyrotoxicosis was extremely important and beneficial to the patient; she believed that there were two types of cases, in one of which the psychic trauma was predominant. Dr. D. C. HARE referred to the danger of delayed operation in certain cases in which the nervous manifestations were alleviated by medical treatment but in which the cardiac damage was progressive. She wondered whether too large doses of iodine were not often given; she had had good results from giving one minim of Lugol's iodine three times a day. Dr. MOORE described a case in which iodine treatment had been most successful.

Dr. AITKEN, in reply, agreed with Miss Hall that an unhealthy nasal condition was often neglected, and that this neglect possibly accounted for the disappointing results obtained from tonsillectomy. She agreed that psychic trauma was an important aetiological factor in thyrotoxicosis, but held that, once the thyroid secretion had been altered, psychotherapy was not likely to effect a cure. She believed that too large doses of iodine were often given.

TREATMENT OF OBSTRUCTED LABOUR

At the meeting of the North of England Obstetrical and Gynaecological Society, held in Liverpool on December 15th, 1933, Professor A. LEYLAND ROBINSON delivered his presidential address entitled "Ancient and Modern."

He described the ancient and modern methods of treating obstructed labour, and said there were four distinct epochs or phases through which the present treatment had evolved. During the first epoch, which extended from the dawn of civilization to the time of Ambroise Paré, cephalic version and embryotomy were the methods of choice for dealing with mechanical obstacles. The second epoch, which began with the teaching of Paré and terminated with the "publication of the forceps," was dominated by the teachers of the French school, who introduced and practised podalic version and accouchement forcé. The third epoch coincided with the use of the forceps which had been invented by Peter Chamberlen at the end of the sixteenth century, but had remained a family secret for nearly a hundred years, only coming into common use in England when Chapman published his book in 1773. The fourth epoch, the present age, dating from about 1880, was initiated by the discoveries of Pasteur and Lister, whose work had rendered the operation of Caesarean section comparatively free from risk, and had thus paved the way for the safe employment of surgical methods of delivery.

The president then discussed the different methods now in use, including forceps, induction, version, craniotomy, and Caesarean section, and drew attention to the great importance of delivering the patient at the first attempt. He showed from an analysis of a large number of cases abstracted from the reports of the British maternity hospitals that repeated attempts at delivery had a marked effect upon the maternal mortality, and emphasized that the "failed forceps" type of case was also found among patients submitted to induction, version, and Caesarean section, and that such failures might be grouped together as "the failed first attempts," and they contributed largely to the available fraction of the maternal mortality. He thought these failures were due to two main causes: (1) lack of knowledge concerning the best method of overcoming a mechanical difficulty, (2) want of judgement in choosing the right time for surgical intervention. The present methods and results were undoubtedly greatly superior to those of the eighteenth and nineteenth centuries, but much could be learnt from the great obstetricians of the past, and especially from their knowledge of the resources of natural delivery.

Reviews

GREIG'S DYSOSTOSIS

Among the features which distinguish the extinct type of humanity, known as Neanderthal Man, from modern humanity, is the possession of a torus supraorbitalis. Dr. DAVID M. GREIG, conservator of the Museum of the Royal College of Surgeons of Edinburgh, has published an exact and illustrated account of a modern skull, in which the supraorbital ridges form a perfect torus supraorbitalis. This modern skull also reproduces another Neanderthal feature—namely, the nuchal ridge of bone known as the torus occipitalis. Under a bizarre exterior this modern skull—the precise history of which is unknown—exhibits all the essential features of the disorder of growth known as cleidocranial dysostosis. There can be little doubt that the skull so ably described by Dr. Greig represents a rare and unnamed disorder of growth to which we may attach, for provisional purposes, the name of Greig's dysostosis. In his Struthers Lecture Dr. Greig brought another disorder of cranial growth to the notice of medical men, to which he gave the name "hypertelorism"—the outstanding feature being the wide separation of the orbits. This condition, which some regarded as an individual abnormality, proved to be a specific disorder, five cases having been recorded in America since the publication of the Struthers Lecture. We have no doubt the condition which Dr. Greig has now described will prove to be a distinct pathological entity. The excellent and exact drawings which illustrate Dr. Greig's monograph should leave his readers in no doubt as to the nature of this unnamed disorder.

"STARLING'S PRINCIPLES OF HUMAN PHYSIOLOGY"

The publication of the sixth edition of this well-known work on human physiology¹ will be greeted by students and teachers alike as fulfilling in high degree the necessities imposed by the examining bodies all over the country. The high standard as regards both treatment of the various aspects of the subject and the general format of the book leaves little to be desired, and Professors Lovatt Evans and Hartridge have added lustre to it by careful revision and by bringing those chapters up to date where increasing knowledge has left former editions somewhat behind the times.

The production of a work of value on physiology is a matter of extreme difficulty for many reasons, but chief among them, we think, is the fact that final knowledge has been attained in so very few fields that one has to choose between a dangerous dogmatism or a vacillating scepticism. The facts of physiology are based on experiments, and the methods of measurement are often so imperfect that interpretation is liable to all sorts of errors. On the other hand, in certain fields the methods are of such a precision that one wonders what relation the final results bear to the kind of information which is really of value to the investigator of the human body. From the point of view of the purely academic worker it is, for example, of great interest to know the exact time relations measured in thousandths of a second of

but it is rather surprising that he makes no mention of the recent work in this country, which tends to show that seborrhoeic dermatitis is a monilial infection. We must conclude with a word of approval of the excellent photographs both of clinical manifestations and of microscopic features with which this volume is amply illustrated. The book is fortified with complimentary introductions by two distinguished American dermatologists, Dr. Schamberg and Dr. Howard Morrow. We are able to endorse their commendation.

THE SPLEEN AND ITS DISORDERS

The intense clinical concern shown by French workers in the subject of splenomegaly and the splenic anaemias is well known, and leads us to examine with much interest any new ideas they may put forward on the matter. A recent book,* written by a French physician in Algiers, deals not only with the splenomegalies which occur in northern Europe, but also with enlargements of the spleen associated with malaria and kala-azar. Interesting sidelights are thrown on the indications for splenectomy, and a wise commentary on the ligation of the splenic artery indicates the grave effects of necrosis which may follow this operation.

The principal new idea in the book, however, is an attempt to test the blood reservoir function of the human spleen in normal and pathological cases. Radiological evidence with the help of thorotrast shows quite convincingly that the human spleen does contract to effort and adrenaline. This contraction coincides with a slight but definite increase in the red cell count taken in capillary blood from the fingers. In Banti's disease and in haemolytic jaundice this increase in erythrocytes does not occur after the injection of adrenaline. In malaria and in thrombophlebitic splenomegaly a definite splenic contraction occurs after adrenaline, with coincident erythrocytosis. It may be said at once that the clinical value of this test appears to be limited in its present form, but to those engaged in a special study of splenic physiology in man the idea is worthy of closer investigation. The technique of simple radiography of the human spleen, as recommended by Benhamon, does not give sufficiently well-defined shadows to judge of small degrees of contraction of the organ except when the spleen is grossly enlarged. The risks of liver damage attendant on the use of thorotrast are duly emphasized.

The book contains a bibliography mainly devoted to French contributions to the literature, and there is also a useful short index.

INFECTIONS OF THE HAND

For twenty years or more KANAVEL'S *Infections of the Hand* has been a classic, and no work on this department of surgery has ever approached it in completeness or efficiency. The methods advocated by the author as the result of a series of brilliant experiments have stood the test of time and are now universally recognized as sound both in principle and in practice.

In the sixth edition no alteration has been made in the general principles, but the arrangement of the subject-matter has been modified with a view to greater clearness, while the illustrations have been brought up to the high standard of modern reproduction. It is true that the somewhat crude sketches of the earlier editions, coming as they did directly from the hand of Professor Kanavel, possessed a certain personal touch; in the new

edition, however, the illustrations have the advantage of artistic perfection, while this has not been allowed to interfere with their diagrammatic clearness. It would be a truism to say that every surgeon who has to deal with infections of the hand might study this volume with advantage, but we would venture to suggest that he takes a grave responsibility if he deals with such infections without its assistance.

Notes on Books

A series of *New Introductory Lectures on Psycho-Analysis*,* by Professor SIGMUND FREUD, has been translated into English. This recently written volume is intended to be a continuation of Freud's well-known *Introductory Lectures* delivered first at the Vienna Psychiatric Clinic in 1915-16 and 1916-17. The new lectures are not intended to take the place of the earlier ones. They do not compose an independent whole; they are continuations and supplements which fall into three groups concerned with new manipulations of themes which demand further treatment on account of the deepening of knowledge. The two other groups contain actual enlargements of the psycho-analytic field, in that they deal with matters which either did not exist in psycho-analysis at the time of the first lectures, or about which too little was known at the time to justify a special chapter heading.

Dr. ESTHER HARDING has written a monograph entitled *The Way of All Women: A Psychological Interpretation*,† in which she endeavours to show how the psychological problems of women have unfolded themselves as they occur in the various phases of her fate from childhood to "autumn and winter."‡ The author prepared herself to be an analyst by an intensive course of training work with Dr. C. J. Jung. Subsequently she has practised psychotherapy in London, and for the last ten years has been working in New York. The book is written with originality and insight. In an introduction Dr. Jung expresses the view that this book is an important contribution to psychology, as it clarifies the confusion existing in the relationship between the sexes.

The Physician, as Man of Letters, Science and Action,§ is the title of a book by Professor T. K. Moxro, in which he has brought together notes on the careers of men belonging to the profession of medicine who have distinguished themselves in other activities. He has been able to form a collection of a most varied sort, from philosophy to aeronautics, and from science to the Rosicrucian cult. It makes entertaining reading, and the author deserves gratitude for his enterprise and industry; the miniature biographies contain many curious bits of history which will surprise and interest the medical reader.

In Tower Hill as a Pleasance|| the Vicar of All Hallows, Barking, and Mr. Leltwich have depicted the past and foretold the future of Tower Hill and its neighbourhood. The vicar is better known as "Tubby Clayton," and with characteristic enthusiasm he here records what has already been done in connexion with Toc H to improve the conditions of the parish and its demesne, and urges large clearances on Tower Hill, which, it is contended, would be of great and lasting value in improving the amenities of the neighbourhood. Lord Wakefield, who is the president of the advisory body, contributes a commendation. Need we add that money is required as well as good will? We wish these philanthropists and archaeological enthusiasts a speedy attainment of their desires.

Applied Eugenics, by PAUL POPENOE, director of the Institute of Family Relations, Los Angeles, and Professor ROSWELL HILL JOHNSON of Pittsburgh, was reviewed in these columns in our issue of April 2nd, 1921. The authors have now prepared a revised edition,¹² in which many changes have been made in order to include references to the great body of new evidence accumulated since the war. "On the whole," they write in the preface, "the progress of eugenics in the United States since 1918 has been greater than the authors at that time would have dared to hope. If the next decade or two can show as much progress, and at the same time avoid another world war, the eugenic welfare of the human race will be measurably advanced."

¹² *Applied Eugenics*. By Paul Popenoe and Roswell Hill Johnson. London: Macmillan and Co., Ltd. 1933. (Pp. 429; 39 figures, 12s. 6d.)

Preparations and Appliances

WIRE TRACTION APPARATUS

Mr. ROBERT I. STIRLING, F.R.C.S. (Edinburgh), writes:

The wire traction apparatus described below was devised to supply an easy means of applying skeletal traction. The spreader has two arms hinged at the top, and these are separated by turning a blunt-ended transverse screw which passes through the upper part of one arm and thrusts against a groove in the other (Fig. 1). The wire is attached

FIG. 1.

to the ends of the arms by round-ended screws fitting into slight depressions. The transverse and terminal screws are tightened by a double-ended box-key. A range of from three to eight and a quarter inches can be obtained between the ends of the arms. The wires, of specially drawn steel with flattened drill points, are chromium-plated, and are two millimetres in diameter. It was found that wires of lesser gauges cut through cancellous bone with prolonged moderate traction, and on two occasions, in my experience, wires of one millimetre gauge have broken with forty pounds' traction. The thicker wires I employ have maintained traction of three hundred and eighty pounds for several days without undue bending. The strength is such that one and a half inches of the wire will sustain a weight of eight pounds without bending. This has proved to be of great value in instituting traction on the arm in such conditions as fracture-dislocation of the head of the humerus, fractured shaft of the humerus, etc., the wire being passed through the upper part of the ulna between the incisura semilunaris and the posterior border in the direct line of the humeral shaft, the elbow being flexed at right angles. If an initial strong pull is desired the spreader is used. Thereafter the spreader is detached and the wire is cut so that only two inches protrude at each side of the olecranon. It is then bent into a U with right-angled corners. The ends are bent back to form hooks over which a traction chain or cords can be placed. By this means a

skeletal pull of five to eight pounds can be easily obtained with a minimum amount of impediments when using a Thomas, Jones, or "acropole" splint. For the introduction of the wires an ordinary hand drill with a chuck is used. To prevent the bending—and therefore maldirection—of the wire during introduction a modified Schoemaker's guide (Fig. 2) is employed. The inner end of the perforated

FIG. 2.

horizontal bar, which transmits the wire, can be accurately placed against any bony area which can be palpated, and the point of exit can be reasonably accurately marked by the centre of the metal ring on the movable pillar.

The whole apparatus has been made for me by Messrs. J. Gardner and Son, surgical instrument makers, Forrest Road, Edinburgh.

AN EXTRACTOR AND MODIFICATION OF THE SMITH-PETERSEN PIN

Mr. R. BROOMHEAD, F.R.C.S. (Leeds), writes:

When I showed some patients who had been treated by the insertion of a Smith-Petersen pin for a high fracture of the neck of the femur at the Royal Society of Medicine on April 4th, 1933, I described a modification of the original pin and also an extractor for removing it, either at the time of the operation if the aim is not correct, or later if it is thought desirable to remove the pin when bony union has occurred. The original pin had a round head that was difficult to grasp. I therefore had a V-shaped groove cut so that the head could be much more easily held by a clamp. The accompanying diagram shows how the shape of the head has been altered and improved.

The extractor is made with a clamp to grasp the head of the pin. The clamp has two limbs, with a spring between to separate them when they are released from the body of the extractor. The limbs are fixed to a threaded shaft, which can be screwed up and down inside a cylinder so that the pin may be withdrawn into its cavity. Counter-traction is obtained by pressure of the distal end of the instrument against the lateral surface of the great trochanter of the femur, and it is necessary to make the instrument fit closely to the bone. The distal end of the extractor is thickened to make a broad area for counter-traction; it is curved to accommodate

the circumference of the femur; and, as the neck of the femur is at an angle of 125 degrees with the shaft, the lower margin of the butt of the instrument is cut away, while the upper margin is prolonged to enable the instrument to fit snugly against the shaft of the bone. The handle is made broad so that it can be grasped easily, and does not catch the operator's rubber glove.

The difficulties of an operation are much diminished by the use of these instruments, as it is necessary to remove the pin if the first aim has been incorrect—a manoeuvre which cannot be done satisfactorily without the extractor and the modified pin. I showed the instruments to Dr. Smith-Petersen when I was recently in Boston, and he is now using them himself to the exclusion of those of his own design. The instruments were made for me by Chas. F. Thackray, Park Street, Leeds.

ONE HUNDRED AND SECOND ANNUAL MEETING
of the
British Medical Association
BOURNEMOUTH, 1934

THE one hundred and second Annual Meeting of the British Medical Association will be held in Bournemouth next summer under the presidency of Mr. F. W. Ramsay, M.D., F.R.C.S.Ed., consulting surgeon to the Royal Victoria Hospital. The Sectional Meetings for scientific and clinical work will be held on Wednesday, Thursday, and Friday, July 25th, 26th, and 27th, the morning sessions being given up to discussions and the reading of papers, and the afternoon to demonstrations. The Annual Representative Meeting for the transaction of medico-political business will begin on the previous Friday, July 20th. The full list of presidents, vice-presidents, and honorary secretaries of the sixteen Scientific Sections will be published in an early issue of the *Supplement*. Other details of the arrangements for the Annual Meeting will appear in subsequent issues. The Association last met in Bournemouth in 1891. We publish below the first of a series of descriptive and historical articles on the town and its medical institutions.

BOURNEMOUTH AND ITS ATTRACTIONS

Bournemouth, the fair and salubrious, has risen out of the ashes of a prehistoric population whose relics are found even to the present day. At the Boscombe Library there is exhibited "a stone celt found at Boscombe, some eight feet below the surface, and supposed by Geikie to be at least 500,000 years old." Within the widening boundary of the town, and over a wide stretch of Dorset and Hampshire, the earth is a sepulchre, and the antiquary will discover a soil rich in objects of archaeological value waiting to be unearthed and mused upon. In recent times, both within and without the county borough, fragments of pottery, urns, flint celts, arrow heads, pins, bracelets, and other antiquities have been found. Even in Talbot Woods, in the very heart of the town, barrows exist as a monument to the ancient Britons, one-time inhabitants of the place, who lie buried there. In the words of Thomas Hardy: "Within the space of a mile from its outskirts every irregularity of the soil is prehistoric, every channel an undisturbed British trackway; not a sod having been turned there since the days of the Caesars." History relates that the first Roman defeat in Dorset happened near the Bourne stream, where 500 men under Caius Marius were ambushed and ruthlessly put to the sword. From prehistoric times great natural forces have compelled the formation of the terrace upon which the town is set—the gravel soil, the chines, the cliffs, and the wide sweep of sand and bay; and during the past century the growth of vast numbers of pine and other trees has secured for the town many of its climatic advantages and much of its natural beauty. Now we have grown up "a new world within an old one."

Bournemouth is set like a jewel on the cliffs at the extreme south-west corner of Hampshire, almost midway between the ancient towns of Poole in Dorset and Christchurch at the mouth of the Hampshire Avon. These two coastal towns lie apart about nine miles. The town lies upon a tableland, which runs up to the edge of the cliffs eighty to one hundred feet above sea-level, and along the several sheltered chines which here and there break the cliffs and run down to the sea; it occupies a commanding position, open to the sea breeze, facing full south, and overlooking a fine sweep of bay and sands extending twelve miles from end to end. On the east the town is sheltered by the Isle of Wight, on the west by the "Isle of Purbeck," and on the north by pine-covered land overlooking the ocean.

The town owes its name to its situation in and about the mouth of a wide, extensive valley, through which

runs a stream, the Bourne, on its way from Kinson, some five or six miles distant, to the bay. Early in the nineteenth century the first house was built in the shelter of this valley, which had until then numbered as its inhabitants a few fishermen only and several smugglers. Soon afterwards, on the eastern side of the valley, building was begun on an extensive scale, the foundation of the town being thereby laid, and the first garden city brought into being. The picturesque planning of the town with the ample provision of open spaces—which can best be viewed from the air—had, been so admirably conceived and executed, and continued with such vision, that the natural features of the place have been preserved and made to harmonize with the needs of a rapidly growing population. Truly, in the words of Sir Thomas Browne: "Art is the perfection of Nature"; and the elegant detached houses, the sheltered gardens, the profusion of flowers and foliage, and the quiet atmosphere lend beauty and dignity to the place, and bring pleasure to the eye and peace to the heart.

In its very newness and cleanness the town has much charm, and if there is the lack of a known historical past, there are compensations in the naturally beautiful character and position of the town, in the wide bay backed by cliffs broken at intervals by green and lovely chines, and in the outlook of a wide horizon and broad expanse of sky. There are four miles of undercliff drive, five miles of overcliff, and many miles of walks by sea, cliff, and in gardens where one may wander amid green lawns and by the quiet waters of Bourne and Stour. Because of the elevated position of the town and the gravel soil natural drainage is good, and speeds up the absorption of rain and flood water, which percolates to a great depth, whence it is hurried by many subterranean channels to the sea. In consequence the soil possesses a high state of dryness and of sanitary cleanliness, and the broad avenues and roadways are kept clean. Such quick drainage gives freedom from ground mists and fogs.

Any day can be observed in the bay the phenomenon of the double tides, which give rise to a peculiar natural ebb and flow. The chief feature is the "second high water." The tidal rhythm along this coast is subject to a curious constant variation: high water occurs at the normal time, but after the ebb has begun its fall is arrested and the tide again rises, usually to a greater height than before, the whole of the ebb being therefore carried out in a resulting shorter space of time. At Bournemouth the double tide may merge into a simple prolongation of the high tide for as long as four hours, the succeeding ebb being completed in the remaining two hours of its

AERIAL VIEW OF CENTRAL BOURNEMOUTH.

(Aeroflms, Ltd., London)

allotted time. As a consequence, during full and new moon, and for a day or two after, a brimming tide may be maintained along the Bournemouth front during the whole of the morning and midday hours. There is a surprising freedom from storms of all kinds, particularly thunderstorms, these being attracted away from the town by the wide expanse of bay, and by the high ground east and west.

Meteorological observations taken at one place in the borough cannot, of course, represent the temperature, rainfall, and indeed the climate of the town as a whole; but the thermometer registers a mean temperature which remains much the same in all parts of the area, although the range will show some variation whereby certain localities will be cooler or drier or more bracing than others. This is actually found to be the case. Southbourne and Westbourne districts of the town and, on the Poole side, Canford Cliffs are found

THE SEA FRONT AT BOURNEMOUTH. VIEWED FROM THE WEST CLIFF.

to be the bracing and stimulating areas of the borough, while central Bournemouth possesses the more soothing sedative climate. In fact, Bournemouth can boast a variety of climates. The long hours of sunshine—there is an average of 1,840 hours each year—the softness, freshness, and purity of the sea air, constitute a combination peculiar to Bournemouth. The absence of smoke pollution and the resulting clear atmosphere in the daytime allow of a maximal penetration of the beneficent light and heat rays of the sun.

Because of the well-known mild winters which the town enjoys, with the rarity of snow, and the evergreens, flowering shrubs, and subtropical plants which grow in the open at that season, it may be thought that the summers must therefore exhibit a relaxing climate. But this is not so. Comparing Greenwich and Bournemouth mean temperatures: in winter, although Bournemouth

shows a temperature considerably higher than that of Greenwich, there is during the hotter months of summer just as consistently a lower temperature. During heat waves there have been occasions when Bournemouth has recorded a temperature lower than that in any other health resort, probably because the gentle breezes from the sea temper the air. In summer Bournemouth often records a night temperature lower than that in many other towns of similar size. This lower night temperature conduces to a more restful sleep;

indeed, for those who suffer from insomnia the sedative climate is well known to prove curative.

Bournemouth is a residential centre of some 117,000 inhabitants, a city of leisure, and of rest and quietness. A large proportion of the residents have been attracted by the quiet amenities of the place. It has always been recognized as a health resort of great value, especially in respiratory disorders, and patients and convalescents with the widest variety of ailments have come in search of health from all parts of the world. The medical

profession and the municipal health authorities constantly strive to prevent disease and to improve the health of the community. On health services alone no less a sum than £43,000 was expended in 1932. It is a striking fact that the death rate is far below the average for towns of like size. For invalids and others who need a warm, mild winter and congenial summer resort there can be no more attractive home retreat than Bournemouth. Many come for rest and change away from the rush and hurry of city life. Others come suffering from a nervous breakdown; a high blood pressure; kidney, heart, blood vessel, or respiratory disease; rheumatism; digestive or metabolic disorder; and it is sufferers from such conditions who are known to benefit most by a stay in Bournemouth.

Few health resorts offer such excellent educational facilities. The Municipal Technical College comprises an art school, recognized by the Board of Education as a centre for training teachers, schools of science, technology, literature, commerce, and domestic crafts, and up-to-date chemistry, physics, electrical engineering, mechanics, and biology laboratories, and workshops. The Bournemouth School for Boys and that for Girls are both municipal: they offer a high standard of education, as also does the High School for Girls, for which new and larger premises are being built in Talbot Woods. Already each of these schools has a very fine record of successes. In and around the town are numerous high-class private homes and boarding schools for boys and girls of all ages. The town is provided with public libraries, which are well equipped and give easy access to books in all departments; there is also an extensive music library containing one of the finest existing collections of modern orchestral scores. This music library attracts visitors from all over the world. The Russell Cotes Art Gallery and Museum has a valuable collection of modern pictures, sculpture, pottery, porcelain, glass, and many native objects from countries in the East. There is a well-staffed general hospital, the Royal Victoria and West Hants Hospital, of 236 beds, with an extension comprising fifty-six beds for private patients of moderate means. Among the places of worship all denominations are represented, and the large number of churches is exceptional; there are in the town several religious and benevolent institutions. The shopping facilities are good, and the shops among the finest in the country.

At all seasons of the year Bournemouth is equally attractive as a health and holiday resort. In summer the normal population is doubled by the influx of visitors, for whom municipal and private enterprise provides everything possible. The many hotels and boarding houses cater for their every wish, and no matter in what numbers they come the town never appears overcrowded. At Easter, in the summer, and again at Christmas, holiday-makers arrive in large numbers. They repair to the piers and beauty spots of the district, and they revel in the warmth of the sun, in the profusion of flowers and evergreens, and in the feast of good music. The town possesses, under the directorship of Sir Dan Godfrey, the finest municipal orchestra in the kingdom. Since the year 1894, when the orchestra was assembled, there has hardly been a British composer of note who has not appeared as conductor of his own works; in fact, many compositions have obtained their first actual production and hearing at the orchestral concerts. The Sunday concerts attract music lovers from all quarters, as also do the Wednesday afternoon symphony concerts held throughout the year, and from time to time broadcast. There is also out-of-door music by the municipal military band, which plays on either of the two piers, or in the central pleasure gardens, or, in inclement weather, in the Pavilion. In 1911 the municipal choir was formed; it consists of 200 selected voices, and has an extensive repertoire. Bournemouth's record in its enterprise for music is unequalled anywhere.

The municipal Pavilion, an imposing building recently completed, is situated on the east side of the central gardens, and is flanked on its west by a superb rock garden, through which runs the Bourne stream. It has a large, airy concert hall, which houses the municipal

orchestra, and in which operas, plays, and variety entertainments are from time to time provided. Here can be heard some of the world's most famous musicians and singers. The Pavilion also possesses a large ballroom, rest rooms, refreshment rooms, and restaurant. In the town facilities are given for sheltered sun-bathing, and for natural sea-bathing. There is a solarium on the pier and other solaria are to be found in private establishments. There are indoor sea-water baths and bathing pool, and before long a large outdoor bathing pool will probably be built. At the present time plans have been drawn, and a scheme is being considered for the provision of a new larger municipal swimming bath and medical baths on an extensive scale in the centre of the town. There are, of course, medical baths at the three private hydropathic establishments in the borough.

In the last twenty years there has been a rapid development of open spaces as parks, gardens, and playing fields. There are 1,200 acres of parks and pleasure grounds, including 170 acres of Hengistbury Head (scheduled as an ancient monument), and about 200 acres in the recently added area of Kinson, which embraces 100 acres of Turbury Common. Perhaps the most sheltered and delightful of the parks are the upper and central pleasure gardens, through which passes the Pine Walk by the banks of the Bourne. There are two eighteen-hole golf courses: one at Meyrick Park (194 acres), where also are hard and grass tennis courts, bowling greens, and various playing pitches; and the other at Queen's Park (173 acres), where also are a horse-riding track and a rifle range. These two golf courses are regarded as the best municipal courses in the country. On the outskirts of the town are six other golf courses all set in charming surroundings.

The public tennis courts number seventy-three, and there are several others at Melville Park and in other parts of the town. Dean Park is given over to cricket and croquet, and King's Park (86½ acres) to tennis, bowls, cricket, hockey, and football. There are also a cycle track and a ladies' bowling club. Altogether there are fourteen bowling greens and several putting greens. Bournemouth possesses four theatres, thirteen cinemas, and a large ice-skating rink. Boating is to be had on Stour and Avon, and from the pier are steamship sailings to the Isle of Wight and along the coasts of Hampshire and Dorset. Motor-coach excursions proceed along smooth tree-lined avenues and roads into the New Forest, the Hardy country, and to the various places of historic interest and natural beauty in the neighbourhood. For those interested in hunting, there are several packs of hounds within easy reach, including the New Forest Hounds and Beagles, and the Portman Hunt. Whether as pleasure or health resort Bournemouth has been well named the "Queen of the South."

S. W. S.

Y. Jimura (*Bull. Off. Internat. d'Hyg. Publ.*, October, 1933, p. 1728) states that the introduction of cerebrospinal fever into Japan is a comparatively recent event. The first records dating back only to 1871. The next outbreak was not until 1887, when several cases occurred in the Army. During the Sino-Japanese war (1875-96) there was a considerable increase in the number of cases. In August, 1903, numerous cases occurred among the prostitutes of Yoshiwara and twenty-seven other places in Tokyo. Subsequently some sporadic cases developed among soldiers who had returned from Manchuria. During the last three years there has been a total of 1,021 cases, or 0.59 per 100,000 inhabitants. Most of the cases were notified in the west of the country, where the temperature was warmer. Rates of 1.66 per 100,000 inhabitants occurred in the urban districts, 0.58 per cent. in the small towns, and 0.29 per cent. in the villages. Most of the cases were in children and young persons; 33.4 per cent. of the deaths took place in the first week and 58.8 per cent. in the second. In most cases recovery occurred in the fourth week. The fatality rate was 79.9 per cent. in cases treated at home, and from 48.8 to 67.3 in cases treated in hospital.

British Medical Journal

SATURDAY, JANUARY 6th, 1934

INFANTS AT SCHOOL

It has been almost axiomatic with this *Journal* that health and education are to be looked upon as two parts or aspects of the same subject. Indeed, it may be said that school instruction consists of three interwoven strands—health training, social training, intelligence training. If this be true of older children, it is emphatically so of little children up to the age of 5 or even 7 years, in whose upbringing the three aims are happily pursued together in this country. One of the most valuable features of the recently issued report of the Consultative Committee of the Board of Education on Infant and Nursery Schools¹ is that it stresses and illustrates this point. It will be remembered that the same committee has already issued two other reports—one on the education of the adolescent (noticed in these columns on January 15th, 1927) and one on the primary school (February 21st, 1931). We indicated at the time the importance of the earlier reports, not only to teachers and those engaged in educational administration, but also to members of the medical profession, whether engaged in the school medical service or otherwise. This is even more evidently true of the latest report.

Discussing the second report two years ago we drew special attention to the medical importance of the chapters and appendices on the physical and mental development of the school child. These are followed up in the present volume by chapters on the development of children up to the age of 7 years and by most valuable memorandums on the anatomical and physiological characteristics of children between the ages of 2 and 7 by Professor H. A. Harris, and on the emotional development of children up to the age of 7 by Dr. Cyril Burt and by Dr. Susan Isaacs. These should be read, especially that by Professor Harris, in close association with the corresponding appendix contained in the report on the primary school. They are not only full of essential and instructive facts, but they illustrate the serious extent to which the subject of growth has been neglected in the education of the medical student during the years devoted to the study of human anatomy and physiology. Two or three sentences may be quoted in this connexion: "The physician or surgeon is often at a loss since he is asked to treat abnormalities or disorders of growth before he is thoroughly versed in its normal features. . . . The results of aberrations of growth in young children are at least as manifest as the results of errors in social adjustment. . . . Growth implies far more than mere change in form and size. . . . Our real interest in

young children is not determined by their anatomical structure, but by their changing activity and behaviour as they pass from one stage of development to another."

The report gives a very interesting account of the history and development of infant schools and nursery schools in this country and the influence upon them of persons and movements in other countries, and there is a chapter on the medical supervision of children below the age of 5 years; this includes some account of the activities of health visitors and of infant welfare centres. The nature and scope of the instruction to be given in nursery and infant schools is fully considered, as is their staffing and equipment. It is strongly urged that the premises should, as far as possible, be on the "open-air" plan. Though the importance of the association of children with one another from an early age is recognized, it is gratifying to be told that, even in this period of small families, "where the home conditions are good, the best place for a child below the age of 5 is at home, particularly if the mother takes advantage of the facilities for regular medical supervision of such children which are available or may be made available in the future," and to have it laid down that "the fundamental purpose of the nursery school or class is to reproduce the healthy conditions of a good nursery in a well-managed home, and thus provide an environment in which the health of the young child—physical, mental, and moral—can be safeguarded."

THALLIUM ACETATE POISONING

The literature of thallium acetate poisoning has been too often reviewed to need recapitulation. It will suffice to recall here a note, with bibliography, on the action of thallium, published in our issue of May 25th, 1929 (p. 962); an excellent account of three fatal cases investigated by Roche Lynch and Scovell² in 1930; the fact that the English Board of Education interdicted, in 1931, the use of the drug in treatment of tinea capitis in school children; and the very good review (also quoting three personal cases of retrolbulbar neuritis) published by Mahoney³ early in 1932. On this subject Ingram⁴ states: "In all, there appear to have been twenty-four deaths from administration of thallium acetate in cases of ringworm of the scalp."

Nearly four years have passed since the occurrence of the most disastrous of all recorded instances of fatal poisoning from this drug—namely, the death of fourteen school children under treatment for ringworm in an orphanage in Granada. Reference was made to this by Lynch and Scovell (in the paper already referred to), who hinted at an excessive dose resulting from an inexact weighing machine, but it was not until August of last year that Professor Alvarez de Toledo y Valero gave, in *Crónica Médica*,⁵ the first full account of this incident in medical literature. It is particularly unfortunate that this author, at the conclusion of an

¹ Report of the Consultative Committee on Infant and Nursery Schools. London: H.M. Stationery Office, 1933 (2s. 6d. net.)

² *Lancet*, 1930, ii, 1347.

³ *Journal of the Medical Association*, February 24th, 1932.

⁴ *British Medical Journal*, 1932, i, 9.

⁵ *Crónica Médica*, August 12th, p. 557, and September 18th, p. 146.

otherwise very informative review of the cases, should have left completely open the question as to whether the disaster was due to overdosage, and if so how it occurred. Those interested in this vital question must be content with the information that post-mortem chemical analysis, undertaken by the State authority, was "successful only from the qualitative point of view," and that the possibility of the drug having changed during storage from the thallous to the thallic salt was eliminated. In the face of such meagre information one cannot but suspect as possible causes for this silence either unterminated legal proceedings or ignorance of the facts. But whether or not the prescription was wrong, the drug impure, or the scales and weighing machine inaccurate, de Toledo gives a sufficiently good account of the symptomatology and course of the illness to merit brief record here.

On February 7th, 1930, at 5 a.m., thallium acetate, obtained from a well-known drug manufacturer, was administered in the approved dose of 8 mg. per kilo of body weight to sixteen children suffering from ringworm. All but two of them subsequently died. The first death occurred two days after administration; there were four deaths on the fifth day, three on the sixth, one on the seventh, two on the eighth, one on the tenth, one on the eleventh, and one on the sixteenth. Symptoms of poisoning are described as follows. Digestive system: acute abdominal pain, glossitis, no constipation or true diarrhoea, vomiting of cerebral type after the fifth day. Cardiovascular and respiratory systems: acceleration of pulse rate only after a few days, respiratory difficulty in some cases, one death in forty-eight hours from bronchopneumonia. Urinary system: decreasing albuminuria in five cases dating from onset of illness, progressive oliguria, and in three cases anuria. Nervous system: profound, early, and persistent somnolence, with occasional evidence of excitement, supranuclear and frontal headache, joint pains from twelve hours after ingestion onwards, muscular clonus in half the cases, persistent tic de salaam in all; loss of corneal reflex (and, in one case, of light reflex), ptosis in six cases, and conjunctival congestion in the majority. Other cranial nerve symptoms included mydriasis, miosis, anisocoria, dim vision, rotatory nystagmus. Other symptoms were pain in the limbs, slight rise of temperature, and cyanosis of extremities and of face. One of the oddest features of the outbreak of poisoning was the delay in depilation—usually expected to be marked between the fifteenth and twenty-second days after administration. In this series none of the fatal cases showed any sign of depilation at all, and in the two survivors the process began as late as the twenty-ninth day. Post mortem, Leche-Marzocchi's sign was positive in thirteen cases. There was engorgement of cerebral sinuses and meningeal vessels, subpleural haemorrhage and congestion of trachea and bronchi, punctate effusions and ecchymoses in the pyloric antrum. Histological examination revealed nothing abnormal in the pons or medulla beyond an increase in the number of nuclei.

SYPHILITIC NEPHRITIS

The occurrence of acute nephritis in the acute stage of syphilis while the secondary rash is developing is well recognized by clinicians but is not common: G. C. Sawyer¹ has recently described a typical case, and states that not a great many examples have been recorded. A goodly number of similar cases must, however, go unrecorded. Thus we happen to know of two typical cases treated during the secondary stage of syphilis within the past ten years. Both of them, as in Sawyer's case, reacted entirely favourably to arsenobenzoic drugs, and thereby were clinically cured and quickly albumin-free, thus giving clinical proof of their aetiology. So there is never any need to hesitate in giving the appropriate arsenical drugs when acute nephritis occurs in the course of secondary syphilis. Rich² draws attention to pathological evidence of the relation of syphilis to nephritis, in a paper entitled, "The Pathology of Nineteen Cases of a Peculiar and Specific Form of Nephritis associated with Acquired Syphilis." It is interesting for physicians to be made to realize, as Rich brings out at the commencement of his paper, how pathology has hitherto failed to confirm the clinical view that the kidneys may be directly affected in acquired syphilis. He quotes from various standard textbooks of pathology, two references from which may be given. Aschoff states: "Multiple scars in the kidneys of syphilitic individuals have been regarded as the results of syphilitic inflammation by the process of exclusion." MacCallum writes: "Changes leading to diffuse scarring and contraction of the kidneys due to syphilis have been said to occur." Rich's paper is therefore of great interest and importance to pathologists as giving perhaps the most definite proof so far offered of a specific renal lesion due to acquired syphilis, thus confirming the clinical view. It is true, as will be seen, that Rich's cases were all in the tertiary stage of their syphilitic disease, but post-mortem evidence in the secondary eruptive stage must be almost impossible to obtain. An important point in considering any renal lesion in late syphilis is obviously to exclude the effects of the potent metallic drugs used in treatment—both mercury and arsenic—and this Rich, from the carefully kept records of Johns Hopkins Hospital, was fortunately able to do. Only nine out of the nineteen cases referred to in his paper had received antisyphilitic treatment at all. Most of the cases recorded were in negroes, but this is accounted for simply by the great preponderance of negroes among the syphilitic patients who are admitted to that hospital. It is not to be inferred that the lesion which Rich describes represents any racial peculiarity, and it occurs in the white race in identical form. The characteristic lesion which Rich describes shows itself macroscopically by the appearance of minute greyish-yellow flecks beneath the capsule and in the cortex. In the early stages no scarring or contraction of the kidney surface is evident, but in later stages scars of varying size in relation to the flecks roughen the kidney surface and distort the cortical striations. Microscopically the lesion is found to consist of dense accumulations of round cells in the interstitial tissue, projecting into and often, therefore, obliterating neighbouring tubules. Many tubules, with their corre-

¹ *British Medical Journal*, 1933, ii, 527.

² *Bull. Johns Hopkins Hospital*, 1932, 1, 357.

sponding glomeruli, may be in this way wholly destroyed. Later, considerable scarring and fibrosis ensue, and crystals of cholesterol, shown as clefts in the paraffin sections, are often abundant. The extent of the lesion, and consequently the extent of the contraction from scar tissue, is very variable. Rich discusses very fully and fairly the contrast between the clinical view of a true syphilitic nephritis and the previous absence of pathological support, and hopes he has now provided, in part at least, the proof which was lacking. The article is accompanied by clear microphotographs of the lesion at its different stages.

VITAMIN D AND FRACTURES

The main facts connected with the curative action of vitamin D in the treatment of rickets are, almost universally recognized, and have been applied to the biological standardization of the various preparations by international agreement. But, as in many other fields of successful therapy, the explanation of the effects is often a matter of great complexity and difficulty. A vast amount of experimental and clinical data is available to show clearly that vitamin D is an essential factor in the mineral metabolism of the body, particularly that of calcium and phosphorus, and it is therefore reasonable to expect demonstrable influences of this vitamin on the rate and efficiency of the healing of fractures. Observations on this subject go back to 1927, and a review of the literature shows somewhat discordant results. While many observers found that various preparations of vitamin D accelerated the rate of consolidation and callus formation in experimental fractures, others reported no effect on the healing of fractures, or even atrophy of the callus and in some cases re-fracture. These variable results could, on analysis, be referred to the great variations in dosage of the vitamin, in the age and species of the animals used, and in the mineral content of the diets employed. It was put forward by Grauer in America that small doses of vitamin D promoted osteogenesis, whereas large doses might produce decalcification and even osteitis fibrosa. Clinically it was reported by several workers that, while fractures in infants and aged subjects were benefited by the vitamin, fractures in ordinary adults were not influenced at all.

The most recent contribution to the problem of vitamin D and the healing of fractures is that of J. Morelle,¹ who set out to investigate by radiological and histological methods the influence of dosage and age of animal on the healing of experimental fractures. Rats and rabbits were used by this worker, and experimental fractures were made either in both tibia and fibula without exposure of the bones, or in the fibula only by exposure and sawing across the bone. Although it was found that therapeutic doses accelerated the formation of a callus, this effect was of limited duration, and seemed to be restricted to the period of cartilage formation. Daily doses of 10 rat units were without effect; 50 to 100 units accelerated the union; but doses of 1,000 units were less favourable in their action. When the dosage was increased to 7,000 and 10,000 units or more a day the formation of the callus was definitely retarded, and this was found to be due to a proliferation of fibroblastic tissue. No effect was

produced by vitamin D given up to the time of fracture and then discontinued, but large doses given three weeks after the fracture definitely retarded the union. These results were obtained with fractures of the fibula. The peculiar fact was established that, if very large doses were given after both tibia and fibula were fractured, the callus formation was accelerated, in contradistinction to the retarding effect if only the fibula was fractured. This is explained by the author as due to the poor apposition in the case of the double fracture, which leads to the formation of connective tissue between the ends, in which cartilage tends to be laid down (Roux), vitamin D being especially active in the deposition of calcium in such tissues. From the clinical point of view we can conclude that moderate doses of vitamin D may help in the treatment of fractures, but more data from the clinician and radiologist must be awaited before it can be thought advisable to recommend a routine treatment.

GROWTH AND DEVELOPMENT

The study of bodily types has been a popular method of investigation throughout the whole period of medical history. In anatomical studies the method has mostly been that of cross section, in which growth in stature, for example, has been measured by comparing the average statures of different, contemporaneously observed age groups. Comparatively few observers have made continuous records of the growth of the same children over several years, and a recent study on these lines by Miss R. M. Fleming attempts to carry out an ambitious programme. The results, as set out in a report² issued by the Medical Research Council, entitled "A Study of Growth and Development," provide a most valuable series of data. For the material upon which the observations are based Miss Fleming visited repeatedly over thirty schools in England and Wales, carrying out her measurements on 2,219 boys and 2,073 girls. Of these over a third were only examined once—an illustration of the great practical difficulty of following a large number of children year by year. Nevertheless, the total number of observations was well over twelve thousand, so that the basis for the detailed statistical analysis carried out by Mr. W. J. Martin, B.Sc., was reasonably comprehensive. The observations taken included in all cases stature, eye colour, hair colour, forehead shape, head length, and head breadth. Children in secondary schools were asked to say what occupation (a) in school and (b) in their leisure time seemed most enjoyable to them. In many cases details were also obtained of the child's school achievements, while in a few schools facial measurements and fuller cranial observations were carried out. In a small number of instances full anthropological measurements of a whole family were obtained, and these are included in an appendix. The general statistical analysis contains a vast amount of important information for the anthropological student. Composite graphs of the principal measurements show at a glance the curious and well-known rhythms of growth, with slower and faster periods. In the present series the fast-growing period for girls starts sooner, finishes earlier, and is less intensive than for boys. The sexes are equal up to 11 years of age; between 11 and 14 girls are taller than boys, but from 14 onwards

¹ *Rev. Belge des Sci. Méd.*, 1933, 1, 481.

² Special Report Series, No. 109. H.M. Stationery Office, 11, Gt. St. St.

the boys become steadily taller than the girls. Stature graphs were found to fall into two main groups—one showing prolonged growth through the "teens," one showing an early stop. This second group could be further divided into a subgroup with steady growth followed by a slowing down and a stop, and another showing a definite burst and a stop, sometimes final, sometimes followed by a slight further growth. Nutrition is obviously an important factor in determining a normal rate of growth, and in one school a somewhat irregular growth curve was traced to the provision of a hot midday meal during the period of investigation. Of the total children examined, over 50 per cent. were of Welsh parentage on both sides, 12 per cent. were of mixed Welsh and English stock, while 21 per cent. were of English stock. This has made possible a discussion of the results under various racial and physical types, and a classification has been adopted with five main divisions according to the value of the cephalic index, each division being further subdivided according to pigmentation into three groups: dark eyes and dark hair, light eyes and fair hair, or light eyes and dark hair. The general survey of the "child population" examined by Miss Fleming on this basis brings out many interesting points. A curious phenomenon was the finding of "pockets" of special physical types in rural areas isolated before the advent of the railway and motor car. A general survey of the psychological features is also included for the whole group under consideration, and Miss Fleming makes a very stimulating attempt to discuss various educational problems in connexion with each of the physical types described. It is impossible to summarize these briefly, for the very reason that the whole object of the work here described has been to study "with even painful attention," in the words of the author, the *individual* features of many hundred records. Although the conclusions drawn must of necessity be largely tentative it is certain that they will be of much value to workers in this important field.

SOME FACTORS WHICH REGULATE THE UTERUS

The demonstration of prolactin in the urine of pregnant women and the success of the Aschheim-Zondek test for pregnancy have stimulated a widespread interest in the study of the effects of the internal secretions on the reproductive organs and reproduction. It is believed that the following substances play an active part during pregnancy: folliculin or oestrin, secreted in the Graafian follicles, progesterin, elaborated by the corpus luteum, the posterior pituitary oxytocic principle, and prolactin. The commercial preparations of prolactin are extracted from the placentas and urine of pregnant women, and there is reason to believe that this substance differs in certain respects from that secreted by the anterior pituitary gland. If the view be accepted that the placenta does not secrete, but merely stores, the active substance, then it must be assumed that prolactin is in some way altered in the body before it is stored in the placenta. Most authorities recognize the existence of prolactins A and B, while some claim that at least four separate and distinct substances concerned with reproduction may be extracted from the anterior pituitary gland. In a paper reviewing the literature and reporting experimental work, read before the ninth British

Congress of Obstetrics and Gynaecology, Blair-Bell, Datnow, and Jeffcoate¹ expressed the view that progesterin inhibited uterine motility during the early months of pregnancy, and that its duties were taken over, in whole or in part, by prolactin during the second half. On the other hand, they believe that oestrin, which increases in amount in the urine during the latter months of pregnancy, causes hypertrophy of the uterine muscle fibres, and sensitizes the muscle or nerve elements to, and stimulates the secretion of, the posterior pituitary oxytocic principle. On these assumptions they sought to offer an explanation of the onset of labour and of certain uterine irregularities. It is evident that these complicated problems can only be elucidated by the experimental method. False results are frequently due to the impurity of the extracts used. It is now known, for instance, that effects attributed to oestrin were caused by traces of protein in the preparations employed. It is, moreover, surely dangerous to make the assumption that the synthesis of results obtained *in vitro* presents a true picture of the manner in which the different activities behave in the body—for example, the uterus of the rabbit, the cat, and the dog respond in different ways to adrenaline. If oestrin behaves in the manner these authors suggest, how is it that Carlton Oldfield² was able to report the case of a pregnant woman proceeding to delivery at term six months after he had removed both ovaries? Then, too, why does the posterior pituitary gland of a male animal contain as much of the oxytocic principle as the female of the same species? The reason why a woman goes into labour ten lunar months after she has conceived has intrigued clinicians for 2,500 years, and it is probable that no authoritative statement could be made to-day which more nearly approaches the truth than the simple view advanced by Hippocrates.

CONTROL OF FURUNCULOSIS IN FISH

Investigations into this widespread disease, occurring among the family *Salmonidae*, have made steady progress since the publication, in 1930, of the first report of the Departmental Committee. The chairman, Professor T. J. Machie of Edinburgh, and his colleagues have done excellent work on fish furunculosis—it exists in various parts of Europe and North America, as well as in Britain—and they are to be congratulated not only on an interesting piece of comparative bacteriology, but on having materially advanced our knowledge on an important economic problem. It is by no means completely solved yet, and in the second interim report³ the committee itself emphasizes the need for further research on many aspects of the general problem: we are confident that this will produce results of value, not only to the science of bacteriology, but to the maintenance of the health of the chief, and perhaps the most palatable, of our game fish. It is now fully established that *B. salmonicida* is the primary and specific causal agent of the disease, and a serological test (complement-fixation) with a specific antiserum has been used to differentiate this organism from related

¹ *Trans. Obstet. and Gynaecol. British Empire*, 1933, xl, 511.

² *Laboratory and Clinical Notes on the System of Gynecology*, vol. 1, p. 66; and vol. 2, p. 43.

³ *Second Interim Report* (June, 1933) of the Furunculosis Committee appointed July, 1929, by the Right Hon. William Adamson and the Right Hon. Noel Buxton, Edinburgh: H.M. Stationery Office, 1933 (2s. 6d. net).

forms, and to show that variations within the species are comparatively slight. A bacteriophage has also been isolated which has a pronounced lytic effect on cultures and has been found in the water of certain rivers. It is acquired exclusively in fresh water, salmon becoming infected in rivers, after they have left the sea, from diseased or healthy trout carrying the bacillus. It is now definitely known that trout may act as infection carriers, maintaining the organism for long periods in a water; these carriers are of the incubating type, and ultimately succumb to the actual disease on an increase of temperature. This last factor has been shown to play a most important part in promoting epizootics, and if fish are in good health a temperature within the range of 55° to 66° F. appears to be necessary for the spread and development of furunculosis. If the health of the fish is poor, however, it may develop at a lower temperature. Under favourable conditions infection is rapid in an infected water—possibly occurring within a few hours—and death may result in three or four days. Fish dying rapidly show practically no external lesions, which tend to develop in the slower infections. Salmon and sea-trout entering fresh water from the sea are highly susceptible. In trout kept in tanks it has been shown that certain factors have a definite influence on the spread and incidence of the disease. Susceptibility depends on species. For example, *S. fario* is more, and *S. irideus* less, susceptible than *S. fontinalis*. Yearling and younger fish are more resistant than older fish; fry are highly resistant, and should be used in preference to older fish for stocking purposes. (The safest plan, however, is to use sterilized ova for this purpose.) Temperatures higher and lower than 60° F. tend to inhibit the development and spread of the disease. When the disease spreads in a colony of brown trout some die rapidly, others resist it entirely, while others contract a latent infection and become carriers, but probably eventually succumb to the active disease. The committee recommend immediate legislative action on the lines suggested in their first report. In rivers, they point out the need for the prevention of overcrowding and the maintenance of general good health of fish, for the removal of both healthy and diseased fish from a water at the commencement of an outbreak, and for early notification of the presence of the disease.

TEAM WORK IN MEDICAL PRACTICE

Mr. W. E. Tanner, president of the Hunterian Society, addressed the members on October 16th last on the subject of the influence of medicine on surgery. He was able to illustrate his text by examples of the need for the association of the physician with the surgeon in many of the problems which are presented to the latter. He also touched upon the subject of "specialism" in general, and expressed his agreement with the view that to be sound this must be founded upon experience in general medicine. Another matter to which he made reference, and one of first importance, was the means that are available for placing the skill of the "specialist" at the service of the public, and he questioned whether the organization of this and of medical services in general was not left too much to the politician and the bureaucrat. Within an institu-

tion it is not difficult to make arrangements so that the skill of a staff may be generally available; success depends simply upon the extent to which advantage is taken of opportunities that are ready to hand. But all must agree with Mr. Tanner that outside an institution organization of this kind is difficult. Under either set of conditions what each patient primarily needs is a "doctor" who will identify himself with his personal interest; in this respect he is better off, as matters stand, outside the hospital, and here at any rate the general practitioner must remain the centre of any service that is to be efficient. Even in these days of elaboration, the general practitioner, as trained in Great Britain, is able to deal satisfactorily with nine-tenths of the ailments of his patients, but in the case of the tenth he needs associates, and the emergency is sometimes difficult to meet both for patient and for doctor. Economically such emergencies should be met by the insurance policy; medically they need team work. No single scheme of team work could be devised which would suit all centres of population; but association between medical men is so much more usual, and professional rivalry is much less stupid, to-day than a few generations ago, that some organization of team work could be devised in most localities. Few would deny that it is in the interest of the patient that he should not, under any conditions, be separated from the services which can be given to him by the general practitioner who has his confidence, or that the duty of organization should be assumed by the medical profession rather than left in other hands.

NEW YEAR HONOURS

The list of medical New Year Honours will be found on page 30. It is not long, and clinical medicine receives scant recognition. Everyone, however, will acclaim the knighthood conferred on Professor Robert Muir, who for nearly thirty-five years has held the chair of pathology at Glasgow University and is known throughout the world as a great teacher and a brilliant investigator in the fields of pathology, bacteriology, and immunology. Sir William Lister, the distinguished ophthalmologist, who is surgeon-oculist to the King's Household, receives the further honour of K.C.V.O. Knighthoods are also conferred on Dr. Frederic Mallett, consulting surgeon to the Bolton Infirmary, for political and public services in Lancashire, and on Dr. Behari Lal Dhillon, chief minister and lately chief medical officer of the Jind State, Punjab. Among the appointments to Companionships in various Orders we may note particularly the C.B.E. conferred on Miss Maud Chadburn, surgeon to the South London Hospital for Women and the Marie Curie Hospital, and on Dr. Helen MacMurchy, lately chief of the Division of Child Welfare in the Canadian Department of Pensions and National Health. Service awards, and special promotions for medical officers in the armed forces, are fewer than usual.

We regret to announce the death of Eminent Professor James Cosser Ewart, M.D., F.R.S., who held the regius chair of natural history in the University of Edinburgh for forty-two years, and of Dr. Swab Vincent, for sixteen years professor of physiology in the University of Manitoba, and for ten years professor of physiology in the University of London.

NEW YEAR HONOURS

The list of New Year Honours was issued as a special supplement to the *London Gazette* on Monday, January 1st. The names of the following members of the medical profession are included.

K.C.V.O.

Sir WILLIAM TINDALL LISTER, K.C.M.G., M.D., F.R.C.S., Surgeon Oculist to His Majesty's Household.

Knighthood

FREDERIC ROWLAND MALLETT, M.D., C.M., Consulting Surgeon, Bolton Infirmary, Lancashire. For political and public services in Bolton.

ROBERT MUIR, F.R.S., M.A., M.D., Sc.D., LL.D., D.C.L., F.R.C.P.Ed., Professor of Pathology, University of Glasgow.

BEHARI LAL DHINGRA, C.I.E., M.B., Chief Minister, Jind State, Punjab States.

C.B. (Military)

Major-General HENRY CHARLES RUPERT HINE, D.S.O., M.B. (late Royal Army Medical Corps), Honorary Physician to the King, Deputy-Director of Medical Services, Southern Command.

C.M.G.

ARTHUR ROBERTS WELLINGTON, M.R.C.S., L.R.C.P., Director of Medical and Sanitary Services, Hong-Kong.

C.I.E.

Lieut.-Colonel ALEXANDER DRON STEWART, I.M.S., Director, All-India Institute of Hygiene and Public Health, Calcutta, Bengal.

Lieut.-Colonel RAM NATH CHOPRA, M.D., I.M.S., Professor of Pharmacology, School of Tropical Medicine and Hygiene, Calcutta, Bengal.

C.B.E. (Civil)

Miss MAUD MARY CHAMBERN, M.D., B.S., Senior Surgeon, South London Hospital for Women; Surgeon to the Marie Curie Hospital.

Miss HELEN MCMURCHY, M.D., lately Chief, Division of Child Welfare, Department of Pensions and National Health of Canada.

FRANK EDRED WHITEHEAD, O.B.E., M.R.C.S., L.R.C.P., lately of the East African Medical Service, and Director of Medical and Sanitary Services, Nyasaland Protectorate.

O.B.E. (Military)

Surgeon Commander KENSLEIGH HILL HOLE, M.B., B.S., R.N.

O.B.E. (Civil)

ROBERT OWEN MORRIS, M.D., D.P.H., F.R.S.Ed., J.P., lately Director of Education, Welsh National Memorial Association.

PETER DONALD STRACHAN, M.D., Superintendent, Lepet Settlement, Botswana, Basutoland.

THOMAS HENRIE MASSEY, M.C., L.R.C.P. and S., East African Medical Service, Senior Medical Officer, Kenya.

BERNARD STEPHAN, M.B., East African Medical Service, Deputy Director of Sanitary Service, Zanzibar.

M.B.E. (Civil)

Captain ASHLEY EDWIN DENBAR HARVEY, Indian Medical Department, Superintendent, Central Jail, Peshawar, North-West Frontier Province.

Kaiser-i-Hind Medal

SARAH ESTONER SHERIFF, F.R.C.S.Ed., Eye Specialist, India.

The following appointments are also announced:

First and Second Class

SARAH ESTONER SHERIFF, F.R.C.S.Ed., Eye Specialist, India.

SARAH ESTONER SHERIFF, F.R.C.S.Ed., Eye Specialist, India.

SARAH ESTONER SHERIFF, F.R.C.S.Ed., Eye Specialist, India.

SARAH ESTONER SHERIFF, F.R.C.S.Ed., Eye Specialist, India.

Australia

[FROM OUR CORRESPONDENT IN SYDNEY]

Jubilee of the Sydney Medical School

The year 1933 is the jubilee year of the Sydney Medical School, and the occasion was celebrated by a gathering of graduates in the Great Hall of the University of Sydney on September 29th. The Chancellor, Sir William Cullen, presided, and among those present were: the Vice-Chancellor, Professor R. S. Wallace, the Dean of the Faculty of Medicine, Dr. C. B. Blackburn, members of the teaching staff of the Medical School, and representatives of all the faculties of the University. Sir William Cullen, Dr. C. B. Blackburn, and Dr. A. E. Mills (formerly dean of the Faculty of Medicine) addressed the gathering. An organ recital was given by Mr. W. McKie, organist of the City of Melbourne, and during the proceedings the members of the Sydney University Musical Society, conducted by Mr. G. Faunce Allman, sang the anthem: "Let Us Now Praise Famous Men." When the University of Sydney was founded in 1850 it was provided that it should be used for the training of students in medicine, but it was not until 1883 that the Medical School was opened. The first dean was Professor T. P. (later Sir Thomas) Anderson Stuart, to whose strength, zeal, learning, organizing and teaching abilities, and remarkable personality the school owed much of its growth, progress, and efficiency. Degrees were conferred on the first six graduates in 1888; since then 2,293 graduates have been admitted. Many distinguished men have been associated with the Sydney Medical School, and have played a part in its development. Among them may be mentioned Sir Almoth Wright, Sir Charles Martin, Sir Alexander MacCormick, the late Professor J. I. Hunter, Professor J. T. Wilson, and Professor D. A. Welsh.

The Rockefeller Building

It is fitting that the jubilee year of the Sydney Medical School should be celebrated by the opening of a new building to house the departments of medicine, surgery, pathology, bacteriology, and obstetrics. The erection of the building was made possible by the munificence of the Rockefeller Foundation, which presented £100,000 to the University for the purpose. But it is doubtful if this splendid gift would have been made if the attention of the Rockefeller Foundation had not been attracted to the Sydney Medical School by the magnificent gift of Mr. G. H. Bosch, which permitted the founding of chairs in medicine, surgery, and bacteriology. The building is adjacent to, and in communication with, the Royal Prince Alfred Hospital. It is approximately 200 feet long by 160 feet in depth, and has five floors. On the western front are two wings containing theatres and teaching laboratories. There is a central octagonal block, on either side of which is a spacious light court. In this central block are the library, pathological museum, and animal house, the latter on the topmost floor. The remainder of the building, constituting its main bulk, consists of research laboratories. The Rockefeller Building was opened on September 28th, 1933, by Air Vice-Marshal Sir Philip Woolcott Game, Governor of New South Wales, and Visitor to the University of Sydney.

A plaque to the memory of Robert Gordon Craig, to whom the University of Sydney is indebted for his gift of £20,000 for the foundation of the Fellowship of Urology, has been placed in the Rockefeller Building. On the occasion of the opening of the new building the widow, Mrs. Craig, unveiled the memorial.

Scotland

Scottish Housing Corporation

A Scottish Departmental Committee on Housing, under the chairmanship of Sir Thomas Whitton, has been sitting since May, 1933, with the reference "to consider what further steps are necessary or desirable to secure the maintenance of a proper standard of fitness for human habitation in working-class houses, other than those suitable for slum clearance, and to promote the supply of houses for the working classes without public charge, through the agency of public utility societies." The committee has now made its recommendations, the chief of which is that a Scottish housing corporation should be established. It is recommended that grants to be paid equally by the State and by local authorities should be given to owners of property requiring to be reconditioned, the grants being up to 50 per cent. of the cost of reconditioning, with a maximum of £75 per house. The houses which would qualify for such a grant would require to have an estimated life of at least twenty years, and the house would have a value not exceeding £300. The subsequent rents of such reconditioned houses would not be left to the proprietors, but would be fixed by the local authorities. The housing corporation, if established, would be given powers, after two years, for compulsory acquisition of house property upon payment of compensation to the owners fixed by the market value of the properties. At the same time private owners would be encouraged to recondition houses by assistance made available to local authorities, public utility societies, and similar organizations. The committee points out that some 200,000 houses, or about one-fifth of the houses in Scotland, would come within reconditioning schemes. It is not suggested that the proposed housing corporation should become responsible for the ownership of this number of houses; the grants would probably encourage owners to recondition about three-quarters of these houses, leaving some 50,000 houses to the corporation to acquire and recondition. On the assumption that an average of £150 would be required for the purchase and reconditioning of each house, a capital expenditure of about £7,500,000 would be involved. One-half of this sum would be met by the grant, and it is proposed that advances should be made to the housing corporation by the Treasury through the Department of Health, the scheme ultimately being self-supporting through the returns from rents. It is proposed that any loss incurred by the corporation might be met by the State, while profits would be put to reserve to meet possible deficits in future years. The rent for such houses, the committee states, should never exceed 12s. 6d. a week, or £32 10s. per annum, and should be fixed in each case by the local authority before reconditioning is carried out. The committee believes that the scheme might be achieved in ten years, and proposes that the grant should be available for five years in the first place, with an inquiry thereafter into the results achieved.

New Edinburgh Maternity Hospital

The ground adjoining the Royal Infirmary of Edinburgh has now been prepared for the site of the new Simpson Memorial Maternity Hospital—which is to be managed as a department of the Royal Infirmary—and it is expected that building operations will begin in the next few months. The new buildings will occupy the site which was previously the playground of George Watson's School for Boys, and accommodation will be afforded for 120 maternity patients. This is a considerable increase on that of the present Simpson Memorial Hospital in

Lauriston Place, which provides some seventy beds. The new hospital will be a quadrangular building five stories in height on its south façade, with a broad balcony facing south on each floor. In the centre of the building there will be a quadrangle, and the north side, of two stories, will house the administrative, service, and out-patient departments. Ample space will be provided for ante-natal clinics, lecture rooms, operating theatres, etc. The nurses' home for the Royal Infirmary, which is to be built later, will stand on a site to the north of the maternity block.

Stirling Royal Infirmary

At the annual meeting of subscribers to Stirling Royal Infirmary Colonel J. C. Dundas, president of the institution, who presided, made special reference to the new contributory scheme which had been introduced by the directors, and of which there were now 10,783 members. When the scheme was started, he said, it was calculated that there might be a loss in contributions from patients of about £600, but actually there had been an increase of £1,900 in income for the year. Expenditure had increased by £542, and the deficit on the year's working had been £64, as compared with £1,444 in the preceding year. There had been ninety-three cases of motor accident during the year, which had absorbed 1,977 "patient days" at a cost of £675. Of this sum only £252 had been recovered, which, however, was larger than in previous years. An extension to the infirmary would be necessary in view of the large surgical waiting list, but as this would involve a capital cost of £6,000 and an annual maintenance expenditure of £2,000, it could not be considered immediately.

Examination of Blood-stains

"Serological Methods in the Detection of Crime" was the title of a recent lecture by Professor John Glaister of Glasgow University before the Edinburgh Section of the Society of Chemical Industry. The examination of a stain, he said, to determine whether it consisted of human blood was a matter on which a definite opinion should only be given by a worker of considerable experience. The method now generally employed was the precipitin test, which was specific for human blood under certain conditions. It was carried out on clear blood serum, and should not be confused with tests depending on the characteristics of red corpuscles. Describing the principle of the test the lecturer said that when defibrinated blood of an animal was injected into a rabbit, the rabbit produced in its body an anti-serum which would precipitate the serum of the animal whose blood was injected or of one closely related to it. Anti-horse serum provided the only exception to the specific character of the test. If human blood was injected, then the anti-serum would precipitate any human blood, but not that of any other animal. In conducting the test the anti-serum was added to a prepared solution, and the appearance within twenty minutes of a precipitate or definite turbidity, spreading from the bottom through two-thirds of the fluid in the tube, was taken to indicate a positive reaction. It was possible, Professor Glaister said, to identify by this test human blood in a stain, even if the stain was many years old or had been treated by heat. The stain was soaked in normal saline for several days if necessary, and the resulting solution had to be rendered clear and neutral. To discover whether blood serum was present in the solution use was made of the fern test. On blowing air into the solution through a fine pipette a persistent foam was produced if serum was present in appreciable quantity. With proper methods a solution suitable for use in the precipitin test could be made from an extremely small blood-stain. Stains of human blood,

which after drying had been exposed to a temperature up to 200°C., would yield a serum solution giving the precipitin test. If drying took place at tropical temperature, however, it might not be possible to obtain such a solution. If a blood-stained cloth was soaked in cold water, either shortly after drying or several weeks later, and afterwards steeped in saline, the presence of serum could be shown both in the water and in the saline. If an old stain was kept in boiling water for an hour, enough serum remained to give a reaction when extracted with saline, but the serum from a twenty-four-hour-old stain could be completely removed by five minutes' boiling. The use of soap in soaking the stain might not affect the removal of the serum, but by producing foam and turbidity it made the precipitin test unreliable. In conclusion, Professor Glaister said that the test could safely be applied to stains on most kinds of wood and leather as well as fabrics and paper, with the limitations he had mentioned.

Royal Edinburgh Blind Asylum

At a meeting of the Board of Directors of the Royal Blind Asylum and School, Edinburgh, on December 26th, 1933, the Rev. Thomas Burns presiding, a scheme was adopted for the reorganization of the industrial department of the institution. The scheme provides that during 1934 no person shall be admitted for industrial training, and that the question of further admissions shall be reviewed annually in December; that the normal age of retirement shall be 55 instead of 60 as at present; and that the establishment staff of blind workers shall be fixed at a total of ninety-nine—eighty-two men and seventeen women—any further blind workers employed by the institution being admitted as temporary workers only. The object of the scheme is to prevent increased expenditure in the future. The wages paid to workers on the establishment staff will be the standard wage as before, with all the benefits and privileges as at present.

England and Wales

Mental Diseases Research Centre in the Midlands

Under the auspices of the City and University of Birmingham Joint Board of Research for Mental Disease a conference of the medical staffs of the mental hospitals in the Midlands was held recently at Hollymoor. Dr F. A. Pickworth, director of the Joint Board, delivered an address in which he emphasized the need for promoting research more actively. He stated that each year about 140,000 persons received treatment for mental disorders in England and Wales at a cost of £10,000,000, of which no more than 3s. in each £100 were devoted to investigating the primary causes of these diseases with a view to their more effective treatment and prevention. This contrasted sadly with the amount of money raised for cancer research, especially in view of the widespread distress caused by mental disorders. There had been in the past an unjustifiable stressing of the hereditary factor, which had given rise to a feeling of helplessness and a reluctance to raise funds for this purpose. Moreover, the existing research workers were seriously handicapped by the imperfect coordination of their activities with those of general medicine. In order to win financial support it would be necessary to demonstrate the economic value of mental research, which were proposed. This required a study of the basic principles of mental research and a survey of the methods and opportunities available. One of the first objects of the conference was the determination of good points of interest and exciting cases, and a point of discussion was that relating to the pituitary

body. An immense amount of routine work would be needed in order to achieve valuable results by indirect methods of research, and the information so obtained would be of inestimable benefit to the hospitals where the patients were under treatment. Viewed from this standpoint the Joint Board of Research had justified itself already as regards the spending of money which it had deemed necessary. It was to be hoped that the importance of the Board's work would be more clearly recognized in the future, and would attract more practical interest and co-operation. Sir Gilbert Barling affirmed his belief that the only way in which an effective research body could be created was the uniting of the mental hospitals in the Midlands in a single scheme, the activities of which would be housed in the University of Birmingham, and would co-ordinate the researches in progress in the various mental hospitals in the area. At the University those engaged in particular investigations in connexion with mental diseases would be brought into close contact with general pathology, physics, and biology, and not be so isolated as heretofore. Sir Gilbert voiced the hope that the various mental hospital committees would in the near future realize the advantages to be gained from such a scheme of co-ordinated research as an important step in promoting the restoration to health of the mentally sick. After some discussion it was decided to appoint a small committee to inquire into the possibility of forming a pathological society of the medical staffs of the Midland mental hospitals as a step towards the establishment of a central research centre.

Reconstituted Public Health Committee for London

The London County Council has been engaged on the very large task of reforming its procedure and the functions of its committees. One result of the proposals will be that the Central Public Health Committee will be known as the Hospitals and Medical Services Committee. Its duties will include the supervision of hospitals and local medical services, the ambulance service, the arrangements for the treatment of tuberculosis and for the diagnosis and treatment of venereal diseases, the control of infectious diseases, examinations with reference to food contamination, the registration of nursing homes, rescue and preventive work, and the direction of medical and nursing staffs generally. It will also discharge the functions hitherto belonging to the Midwives Acts Committee. The work hitherto done by the Central Public Health Committee in respect of dwellings will be discharged by a new committee, to be called the Public Health and Housing Committee, which will have under its control all matters affecting public health not within the reference of any other committee. It will deal with house sanitation, improvement areas, drainage, water supply, and housing matters generally.

Nutrition of London School Children

Inquiries have been made by the school medical staff of the London County Council with the object of ascertaining whether the nutrition of children in the poorer districts has suffered as a result of recent financial stringency. Certain schools in districts where special anxiety was felt have been selected and the ten-year-old age group examined, this group being taken because it is sufficiently removed from any medical inspection age group to ensure that the children would not be subject to action arising out of recent medical recommendations. Altogether, 1,281 children have been examined, of whom 93.5 per cent. were considered well and 6.5 per cent. poorly nourished. Only two children were grossly ill nourished. Among the children whose parents were in full employment the percentage of the poorly nourished was 7.6 which is above the general average for the whole group.

The percentage of poorly nourished children among those whose parents were receiving unemployment benefit was 5.3, transitional benefit, 7.9, and public assistance, 7.5. In view of the fact that the selection of schools and the age group was made with the direct purpose of discovering the worst, it is considered that the percentage of ill-nourished children is surprisingly small and the result of the inquiry reassuring.

New Deep X-Ray Unit for Lambeth Hospital

An enlarged x-ray unit is being installed at the Lambeth Hospital, one of the London County Council's institutions. It has been felt that the important advance made during the last two years in radiotherapy in the treatment of cancer makes it desirable that the new apparatus should be such that full use can be made of recent discoveries. Until a short time ago it was impossible to obtain x-ray apparatus of higher than 200 kV which would stand the wear and tear of everyday work. There are now several plants working satisfactorily at 400 kV. An offer has been made by a British firm to supply such an apparatus to the Lambeth Hospital for three months' trial, and to remove it if it is found not to be suitable. The estimated cost of the apparatus is £4,564, which is said to be considerably less than the cost of German apparatus, including import duty. The estimated cost of upkeep of the apparatus is £1,200 a year.

CORRESPONDENCE

Control of Metastases in Breast Cancer

SIR,—At the recent annual congress of the British Institute of Radiology the subject of the treatment of cancer by x rays and radium was freely discussed by a number of speakers. Some advocated that the cure of cancer was in sight if x rays generated at one million volts were available. Others clamoured for large quantities of radium for treatment of the primary growth. It was remarkable that the word "metastases" was mentioned by but one speaker, and yet it is the want of control of metastases that is the cause of the failure to cure cancer.

There is in existence an Egyptian papyrus dated 2000 B.C. which describes the removal of a tumour from the breast of an Egyptian princess by the cautery, and how the tumour returned and she died from what we now know were metastases. The operator was duly executed, after torture, to make it more interesting. Have we advanced in our treatment of carcinoma mammae since those times? True, we use other agents: true, the operator does not have his head off if he fails. It is only too true, however, that failure in carcinoma mammae must still be attributed to secondary deposits. But few workers can recall fatal results directly from the breast tumour, or even from secondary glands in the axilla or neck. Deposits in the liver, spine, and mediastinum still take their toll, and are the real cause of our failures to cure. This fact and the crude methods of diagnosis at our disposal make it imperative that treatment should be planned on the assumption that the disease is generalized or widespread by the time that it can be diagnosed.

It must be accepted that, even if a means were found to destroy the whole primary growth with absolute certainty, our results in carcinoma mammae would probably be but little better than those obtained in 2000 B.C. Our first surgical lecture teaches us that local removal of the breast tumour is bad surgery—it is puzzling why this teaching is ignored by some radiologists and surgeons when this local removal is accomplished by

short-wave x rays or by surgical implantation of radium needles. It is obvious, therefore, that to secure the destruction of the primary growth must go hand in hand with the destruction and prevention of metastases and recurrences. This is the ideal to be aimed at in all cases of cancer; but can it be accomplished? Briefly, at present, no. This, however, is no excuse for neglecting the problem. It would seem almost as if the word metastases is discreetly avoided by many. I wish to advocate that the research worker should tackle the problem seriously.

It was stated many years ago that cancer grafts in rats (Jensen's rat sarcoma) were less likely to "take" if the animals had been previously subjected to generalized x-irradiations; this is an observation of considerable importance, and further work on these lines is urgently wanted. In fact, it was on this statement that "generalized radiation" for the prevention and destruction of metastases was introduced at the London Hospital some twelve years ago. The introduction of short-wave therapy unfortunately did not help towards solving this problem of the prevention of metastases. It was soon realized that this method was impossible of application in the prophylactic treatment of carcinoma mammae. In the first place, microscopical metastases may be anywhere and everywhere in the body; this makes necessary the use of large radiation fields; consequently the patient is unable to stand the large doses advocated, without damage. Again, short-wave therapy requires delivery of the dose at a definite depth by cross fire—but there is no means of determining what particular area should be attacked.

As a compromise I suggest the following combination of the two methods to be used in all cases of carcinoma mammae; personally I use it in all cases of cancer. The primary growth is removed by surgical diathermy, implantation of radium needles, or by heavy doses of short-wave x rays applied locally, whichever is considered suitable in the individual case. "Generalized" radiation of the whole trunk—that is, to include back, front, and sides—using medium-wave x rays, follows. In all cases dosage should be pushed as far as possible, but so regulated that no serious ill effects are noted. Slight nausea indicates the limit of tolerance or the "saturation" point. This method of generalized radiation, although crude, is at least local, and worthy, I think, of further development.—I am, etc.,

London, W.I. Dec. 27th, 1933.

S. GILBERT SCOTT.

Erythema Nodosum

SIR,—Dr. W. R. F. Collis's article on erythema nodosum, in the *Journal* of December 23rd, 1933, is the most important contribution regarding the aetiology of this disease which has appeared in English literature for many years. It establishes, beyond any shadow of doubt, the relationship of this disease to tuberculosis. This is a matter of the utmost importance, for erythema nodosum is an early symptom of tuberculosis, occurring generally when other physical signs are as yet non-existent.

It is only by the early recognition of the disease that we can hope to combat the grave and very fatal complication. Dr. Collis estimates that only about 15 per cent. of all cases of erythema nodosum are of streptococcal origin, the remaining 85 per cent. being tuberculous, and he dictum that "we should regard every case of tuberculous erythema nodosum as one that should be treated by all engaged in the practice of medicine." Some years ago I wrote: "Erythema nodosum must always be regarded as a danger signal, as a dire warning that

tuberculosis may exist or may develop" (*Erythema Nodosum*, John Wright and Sons, 1928), founding my opinion on the fact that in some 20 per cent. of my cases there was definite evidence of tuberculosis at some period of the patient's history. The higher figures obtained by Dr. Collis are, of course, due to the routine tests he applied—the skin reaction to tuberculin, and the detection of tubercle bacilli by the gastric lavage method. When one recalls the difficulties there are in recognizing the tubercle bacillus—difficulties recently emphasized by Wilson's Report to the Medical Research Council (No. 18)—it seems possible that the percentage of cases ascribed to tubercle may be found later to have been unduly high.

As one who has persistently maintained that erythema nodosum is a definite specific fever, due to some variety of streptococcus, I am still unrepentant, and regard Dr. Collis's results with streptococcus endotoxin (of which he kindly sent me a supply) as confirming this view. I could have wished, however, that the word "rheumatic" had been omitted from this report, and in all cases the word "streptococcal" substituted.

Gradually the group of erythematous diseases is being cleared up, just as the so-called rheumatic diseases have been reclassified and defined. Whether there be, or not, a separate disease, erythema nodosum, due to a definite variety of streptococcus is a matter of minor importance. The real practical point is that all clinicians shall recognize that erythema nodosum is in the main a condition associated with tuberculosis, and cease to regard it as a skin disease or a manifestation of rheumatism.—I am, etc.,

Clifton, Bristol, Dec. 20th, 1933

J. O. SYMES.

Pharyngeal Haemorrhage

SIR,—I was interested in Dr. P. Shackleton's two cases of pharyngeal haemorrhage recorded in the *Journal* of December 23rd, 1933 (p. 1167). Severe and sometimes fatal haemorrhage arising from a tonsil abscess is rare, but several cases have been recorded.^{1 2} I have seen only two cases, and another of aneurysm of the internal carotid in a boy of 8. The aneurysm followed the incision of a tonsil abscess. The boy nearly died of haemorrhage, and had a temporary hemiplegia. The haemorrhage is due to an erosion of a large vessel, and not to the incision of the abscess. The incision has been unjustly blamed.

Erosion of the internal carotid is more likely to occur when there is a siphon bend of the artery, bringing it into an abnormal position immediately behind the pharyngeal wall and posterior pillar of the fauces. This is the site of a lateral retropharyngeal tonsil abscess. In such cases of haemorrhage the tonsil should be enucleated and the bleeding point secured. This has been successful in two cases to my knowledge. The bleeding may arise from a large vessel, but not always from the carotids. The tonsil can be enucleated under local anaesthesia, but a general anaesthesia is usually necessary, when morphine and chloroform is definitely indicated, and not ether. If it is certain that the haemorrhage arises from the carotid vessels the bleeding point can be secured by an external incision in the neck, but I have no experience of this method of attack except in war injuries of the neck. That is another story. Incidentally, war injuries of the internal carotid artery sometimes resulted in death from an embolus or vascular lesion of the brain, a possible cause of death in Dr. Shackleton's first case—I am, etc.,

Chilblains

SIR,—I was interested to read Dr. J. T. Ingram's letter in the *Journal* of December 23rd, 1933 (p. 1184). Having used thyroid in small doses (t.i.d.) in the treatment of chilblains for nearly ten years I can confirm its usefulness when restricted to persons not under weight. I have sometimes found it necessary, however, to push the dose a little to get the best effect. For persons who are under weight calcium iodide (gr. jss, t.d.s., p.e.) is useful but not quite so effective. In my own practice I have never appeared to get any convincing results from calcium and parathyroid, or from colloidal calcium injections.

General hygienic supervision is, however, at least as important as any internal or local remedy in the treatment of chilblains. Thus, a well-balanced diet (with additional fats if these can be tolerated by the undernourished patient or a suitable form of them found for her), attention to the bowels, adequate bodily exercise supplemented by limb exercises if necessary, warm under-clothing, warm leg- and foot-wear, and non-exposure of the extremities to excessive heat and cold are all indicated. Even improvement in the housing conditions may occasionally be a factor in the treatment of chilblains; for the fact of a good hot-water, as well as an internal, water supply being available for increasingly large numbers of the population has undoubtedly, I think, tended to lower the actual incidence of chilblains.

Just one word finally as to the assessment of any treatment for this condition. A proper therapeutic test requires a really prolonged cold spell for the establishment of any remedy. How often in this changeable climate of ours does a sudden or a gradual rise of temperature so obviously invalidate our therapeutic results!—I am, etc.,

J. INGLIS CAMERON, M.B., F.R.F.P.S.

Glasgow, Dec. 27th, 1933.

Blood Transfusion in Puerperal Sepsis

SIR,—The letter from Mr. E. Hesketh Roberts published in the *Journal* of November 11th, 1933 (p. 894) is interesting as it helps to explain the dramatic results which attended the treatment of three cases of puerperal sepsis by blood transfusion. This is, of course, recognized as being of value in the treatment of septicaemic cases, but in the literature at my disposal I have been unable to find any reference to its employment as a routine in cases of puerperal sepsis. I have ascribed its success in these cases to the replacement of the volume of blood lost at confinement, and, thereby, to the stimulation of the powers of resistance which had been lowered by this loss. This I think partly agrees with the theory and facts as expressed by Mr. Hesketh Roberts.

My first case occurred three years ago, when, after manual delivery of the placenta, sepsis developed on the fifth day, and in spite of treatment the hyperpyrexia continued and the condition was grave. A blood culture on the ninth day gave a growth of short-chained streptococcus, and the patient was given 500 c.c.m. citrated blood on the tenth day with 50 c.c.m. anti-streptococcal serum. On the twelfth day of illness the temperature fell to normal, and continued so for the remainder of her convalescence, the only complications being two pyaemic abscesses, one in the upper arm and the other in the vulva, which, on being drained, cleared up. The second case was seen at the end of the second week of illness after treatment with intrauterine glycerin, colloidal iodine, etc., and was complicated by a *B. coli* cystitis. Blood culture on the eighteenth day was sterile; 500 c.c.m. of citrated blood was given on the twentieth day, and on the twenty-third day of illness the temperature fell to normal, after which convalescence was uneventful. The

third case developed sepsis after a Caesarean section. The condition was critical on the sixth day, and the patient was given 400 c.cm. of citrated blood while in a delirious and semi-conscious condition. Temperature fell next day to normal, and she was sitting up in bed reading after forty-eight hours. Convalescence was, however, complicated by the development of an extra-peritoneal abscess round the site of the abdominal scar, which nevertheless settled down after drainage.

It is not suggested that blood transfusion should be regarded as a specific or only employed as a *desideratum* resort in critical cases, but it is thought that its employment would appear to have some physiological justification, and at any rate should do no harm.—I am, etc.,

Rawalpindi, N. India, Dec. 9th, 1933. M.B., B.S., Major R.A.M.C.

Use of Quinine in Normal Labour

SIR,—On reading Dr. Douglas Mitchell's letter in your issue of July 15th, 1933 (p. 126), I determined to try his method of giving small doses of quinine during the last few weeks of pregnancy.

In November I was consulted by a primigravida, aged 21 years; last menstrual period was one week late, and occurred at the end of March; general build slight; teeth all perfect; pelvic measurements normal. She did not come, as directed, to see me again four weeks later, but on December 7th sent for me. At 2 p.m. she had experienced some discomfort "in the back passage" and had a bowel motion. At 4 p.m. she had slight recurrent pains; at 5.40 she delivered herself of a female child weighing 6½ lb. The child was delivered by one long continuous pain, which expelled all the uterine contents, including placenta. The nurse, who was present, stated that she hardly seemed to be in labour before this pain occurred. The birth was followed by a fairly brisk haemorrhage for five to six minutes, controlled by pituitrin, and her subsequent history was entirely uneventful.

Had I administered the doses of quinine I should have been much impressed by the easy labour that followed such treatment. I may add there was no doubt that the patient was a primigravida.—I am, etc.,

A. G. HAWTHORSE ENGLISH.

Bakerland, Dec. 21st, 1933

Vision of Colour and Brightness

SIR,—I have read with the greatest pleasure the report of Professor Haldane's lecture in the *British Medical Journal* of December 23rd, 1933. I have for many years given similar demonstrations to the Physiological Society and elsewhere without anyone disputing the facts, and with the same conclusions. These facts were predicted by my theory of colour vision (see "Simultaneous Colour Contrast," *Journal of Physiology*, 1911; "Simultaneous Colour Contrast," *Proceedings of the Royal Society*, 1912; "Colour Adaptation," *Proceedings of the Royal Society*, 1913; *Physiology of Vision*, G. Bell and Sons, London, 1920).—I am, etc.,

ROBERT T. S.W.I.,
Dec. 26th, 1933

F. W. EDELMAN-GREEN.

SIR,—Professor J. S. Haldane, in his interesting address (*Journal*, December 23rd, 1933, p. 1158), admirably refutes mechanical materialism, but in doing so he unfortunately falls into the camp of idealism. Materialism today has progressed considerably since the days of the French mechanical materialism, with its ponderable matter like

billiard balls and its knowledge of absolute truth. Materialism today simply states that objects exist independently of our sensations, and then give us a correct reflection of this objective reality, proceeding to with relative truths.

Professor Haldane states that we cannot find consistency, which is the mark of truth, in the supposed correspondence of our sensations with an objective world existing apart from our sensations. He also states that our physical and mathematical interpretation of phenomena is only partial and abstract. Naturally we agree that these interpretations are only partial—that is, that biological phenomena can never be fully explained by physical, chemical, and mathematical means only. We must also use, as Professor Haldane states, "the biological conception of life" in our interpretations, but we deny that these interpretations are abstract and have no mark of truth. These physical, chemical, and mathematical interpretations are true reflections of objective biological reality. The mere fact that we can use these interpretations for our own purpose in practice points to their correspondence to objective truth and reality, for if our interpretations of them were at all divergent from their objective existence then we would fall in our use of them, and only then would "Nature mock at us."

To take the example of brightness and colour: although Professor Haldane states "we cannot have any objective measure or standard of brightness and colour; we can only have a 'human' measure thereof," we must realize that our human measure and standard gives a true, if only approximate, measure and standard of reality, as evidenced in our use of these standards with success in our practical day-to-day life. If, for instance, a new colour or degree of brightness is discovered existing in Nature to-morrow, by means of any instrument, surely it does not imply that the colour or degree of brightness did not exist yesterday because we did not perceive them. We are thus constantly making and renewing our standards, which, although relative, are continually approaching absolute reality as our knowledge advances with the progress of the human race.

Professor Haldane concludes by co-ordinating objective and subjective worlds in his biological interpretation of phenomena. Unfortunately his theory is an idealistic one, for his objective and subjective worlds are both spiritual—that is, mental—in form. His physical is an abstraction from the biological, the biological is an abstraction of the personality or psychological, and the individual personality is derived from the divine personality; thus, after a whole series of abstractions, we come to the supreme abstraction. Professor Haldane thus teaches that mind is the prime, and matter is derived from it, whereas the biological sciences and the law of evolution prove that mind is derived from matter. With the growth and evolution of the nervous system in animals we find simultaneously the growth and evolution of the mind, until now, in man, it has become the highest function of matter—that is, the brain.

We may well ask Professor Haldane what was the interpretation of the world millions of years ago, when the world was a molten mass and no life existed therein. The answer, I suppose, would be, "The Creation story"; and at the time of the Deluge the answer would be, "That of the Ichthyosaurus plus the Creation." Until we realize that matter is the prime and mind is derived from it—until we recognize the existence of an objective reality and our approximate interpretation thereof—we shall find scientific thinking tending to stop.—I am, etc.,

LESLIE, F.R.S.E., F.R.C.P.

S. 1111

The Nutrition Report

SIR,—May I point out that the reference of the B.M.A. Committee on Nutrition was "To determine the minimum weekly expenditure on foodstuffs, etc."; also that (*Supplement*, November 25th, 1933, p. 13) it is claimed that the costs are based on mean figures furnished by medical officers of health. This being so, the criticisms of the report in Dr. Mackay's letter (December 16th, 1933) are justified, and your annotation in the same number does not answer them. The price of milk given in the report is 2½d. a pint; a retailer who sells milk at less than 3½d. a pint is liable to a fine of £50. The price given for an egg is 1d.; eggs can be obtained at this price only for a few weeks in the year. These cannot be regarded as "mean" prices, if mean is used in the sense of average. These gross instances, and others given by Dr. Mackay, raise suspicions concerning all the prices. For example, the prices given for meat appear to be those of meat with bone, while the food values are those of meat without bone. Moreover, this report cannot be regarded as an academic exercise, *in vacuo*. It must be taken in its practical applications, especially with regard to the adequacy of unemployment benefit and relief. In this connexion it has already been quoted widely, without qualification. It is therefore unfortunate that the prices on which the costs of the diets are based are most untrustworthy.—I am, etc.,

Sawbridgeworth, Herts, Dec. 24th, 1933. JOHN MARRACK.

* We welcome this criticism of the report of the Nutrition Committee, for it enables us to make certain points clear in regard to the practical use of the report. Our correspondent does not fully realize that there can be no universally applicable figure for the minimum cost of adequate food. If any such figure had been proposed by the committee it could only have applied to the particular markets studied and at the particular time when the prices of commodities were ascertained. Variations in price may be due to the locality, market, or season, or to the operation of economic factors of supply and demand. On page 17 of the report the committee recorded the opinion that "no single figures for the minimum cost can be regarded as generally applicable." A range of cost was therefore given, based on the Stockton figures as the lower limit and the mean cost of foodstuffs furnished by medical officers of health, but it was observed that "even higher figures might apply to certain localities." In anticipation of such criticisms as those of our correspondent and Dr. Mackay, the committee was at pains to point out that only by ascribing local prices to the commodities listed on the minimum desirable diet scales can the appropriate minimum weekly expenditure be calculated for particular individuals and families from time to time. The question of unemployment relief was not the committee's concern.—ED., B.M.J.

Compound Fractures of the Tibia

SIR,—I am relieved to find that Mr. Simpson-Smith's advocacy of immobilization of the ankle in the equinus position in fractures of the shaft of the tibia has not escaped condemnation, and I would endorse Mr. Tippet's comments. There are a few bone and joint injuries in which it is essential to hold the foot in the position of full equinus (backward dislocation of the ankle with anterior marginal fracture of the tibia, and dislocation of the subtarsal joint with fracture of the neck of the astragalus). In fractures of the shafts of the leg bones, on the other hand, the equinus position is entirely unnecessary, it delays recovery, and it may be responsible for a slough. If the ankle is allowed to stiffen in the position of equinus a considerable period of treatment is

necessary before full dorsiflexion is regained, and during this period there is constant strain at the site of fracture. Unless the fracture has been immobilized for such a long period that consolidation is already quite complete, the efforts of the patient to put the heel to the ground, and of the masseuse to push the foot up into dorsiflexion, are calculated to produce the very backward angulation of the fracture which Mr. Simpson-Smith is attempting to avoid. The association of an unconsolidated fracture of the lower shaft of the tibia angulating backwards, with an ankle-joint stiff in equinus, is unfortunately not infrequently seen, and presents considerable difficulty in treatment.

It must be acknowledged at once that Mr. Simpson-Smith's difficulty is a very real one, and he is to be congratulated on again drawing attention to the fact that it is the attempt to secure right-angled dorsiflexion which is responsible for the backward angulation so frequently seen, particularly in low oblique fractures of the tibia. The problem is not to be solved, however, in the way he suggests, but by applying traction to the heel with the limb hanging vertically during the application of the plaster. Traction applied behind the ankle-joint will at the same time dorsiflex the foot and correct the angulation. It is in this type of case that the "tibia traction apparatus" I have described (*British Medical Journal*, June 11th, 1932) finds its most useful application.—I am, etc.,

Liverpool, Dec. 24th, 1933.

R. WATSON JONES.

Anaesthetic Deaths after Basal Hypnotics

SIR,—I was interested to read Dr. Graeme Bentliff's letter in the *Journal* of December 23rd, 1933, and thank him for his very kind reference to me. I am inclined to agree with his view that the addition of morphine or its derivatives to the barbiturates increases the risk attaching to the latter, probably because it delays their excretion. In the case to which Dr. Bentliff refers it certainly appeared to do so. On the other hand, the combination of morphine with the barbiturates is so generally used—and in the large proportion of cases with impunity—that few, if any, professional anaesthetists can have a long series of cases in which barbiturates alone were used which could be compared with a second series of cases in which the barbiturates were combined with morphine. Dr. Bentliff's experience is founded on a comparison of this nature, but a large number of cases are required, I think, before one can be dogmatic.

The fact is, Sir, that in this imperfect world nothing worth having can be bought for nothing, and the advantages of basal hypnosis as a preliminary to anaesthesia are purchased by a certain increase in the risk—small, I agree, but very definite nevertheless. No doubt increased experience, improved preparations, and, above all, a simple and reliable means of testing beforehand the vital value of the renal and hepatic cells (if such can be invented) will diminish the risk, but I doubt if we shall ever reach that ideal state when benefits received are entirely free of cost.—I am, etc.,

London, W 1, Dec. 29th, 1933.

HERBERT CHARLES.

SIR.—The letter by Dr. Graeme Bentliff of Jersey is extremely interesting. In my opinion there is a reasonable explanation for most of the trouble, and I think "luck" can be definitely ruled out. Most of the patients had morphine as well as the barbiturate: both depress respiration—the morphine perhaps more than the other. Consider the morphine first. It is a well-known fact that exophthalmic goitre cases and "plus-thyroid" patients will take a large dose of morphine with a minimum of effect; they take all basal anaesthetics, avertin as

well as the barbiturates, extremely well; hypothyroid cases give one anxiety with even a very small dose of morphine. It seems to me probable that the cases which gave trouble were, in some degree, deficient thyroid ones. If the basal metabolic rate is taken it is probable that these susceptible cases can be identified, and precautions taken. Animal experiments may be misleading: I have seen a dog weighing about 4 c. given 10 grains of morphine, and he was only drunk after eight hours. The veterinary surgeons give 1 grain to a terrier weighing 20 to 28 lb. as a usual dose for therapeutic purposes! I agree with Dr. Benthif that basal hypnotics give the most pleasant anaesthesia possible in the present state of our knowledge, and should be more extensively used than they are, but to be safe there should be much more preliminary investigation done than is usual. One great obstacle is that the anaesthetist rarely sees the patient before he or she comes into the anaesthetic room, and afterwards too often not at all. When there is an operation list of ten or twelve there is difficulty in having them all adequately watched during the prolonged sleep which usually follows most of the basal hypnotic anaesthetics. Very few anaesthetists will say that the intravenous route is safer than the oral, although it may give some indication of a patient's extra sensitivity to hypnotics. Until we breed a standard race of people I am afraid all these "one shot" body-weight doses will be fraught with a considerable amount of risk.—I am, etc.,

E. J. CHAMBERS,

Anaesthetist, Rochester Hospital and
Dorchester, Dec. 26th, 1933. Dorchester Royal Infirmary.

Serum Reaction for Malignancy

SIR,—I had not intended entering into the controversy about Dr. Cronin Lowe's modification of the Benden reaction at the present stage, and should not have done so had not the experience of others been called for. I have hitherto carried out forty to fifty tests only, and have just discarded all my results, as I have only just standardized my technique. My own results have been unexpectedly confined on two occasions, and though I have apparently been wrong on others the final confirmation is still lacking. I believe, however, that I am beginning to be able to differentiate malignant from non-malignant sera, and I shall continue to carry out the test until I have done at least half as many as Dr. Cronin Lowe, after which perhaps my opinion will be worth having.

It would be a great help if Dr. Cronin Lowe would give the exact details of his method, as the test appears to depend very largely on minutiae, and to be a very delicate one. I have found, for instance, that the method of allowing the blood to clot makes a difference. In my earlier cases I used to allow the blood to stand in a test tube immersed in cold tap water to clot out, but I have since found it better to let it stand at room temperature. I think that if Dr. Allott would adopt Dr. Cronin Lowe's standard method of raising serum and reagent he would not find his precipitates going so far to the left in the "A" row. I had the same difficulty as he had at first. Perhaps care should be taken not to let precipitate be further during mixing. Another difficulty which I have experienced is that I sometimes find the "B" index came out higher than the "A" serum, so that it is impossible to get a numerical ratio at all, and I imagine that Dr. Cronin Lowe has realized the possibility, as he states in *British Medical Journal*, March 11th, 1933, p. 426, "conversely, when the serum index is slightly higher than the 'A' index." Obviously, if the serum index is slightly above the antigen index, reading the "B" row would be the same as for the "A" row, so that one would not be able to express the

ratio numerically, though the interpretation of the test would not be affected. I have had a few cases in which the "C" reading was less than the "A" reading.

I have an impression, which I cannot yet confirm, that both the other and the thermal effects are more marked in young subjects than they are in older ones. I should be interested to hear whether other observers have noticed this. I am myself using a 5 mm. observation chamber with my interferometer, and I do not find the wide differences in readings which others seem to prefer. For instance, I find that my lowest "B" index figure is 34 and my highest "C" index figure is 68, so that all my fractions come out much nearer unity than Dr. Cronin Lowe's figures. Can anyone explain this? In conclusion I would like to submit that Dr. Cronin Lowe's total of 1,700 tests will take a good deal of beating, and that it would be a very great pity if further research were discouraged by adverse criticism based on insufficient evidence and on methods other than those of the creator of this particular modification of Benden's test.—I am, etc.,

C. J. STODOL, M.A., M.D.,

R.C.P.D.P.H., D.P.H., D.P.M.,

London School of Hygiene and Tropical Medicine.

London, Dec. 26th, 1933.

Ultra-violet Rays and Seminal Stains

SIR,—In cases of rape, and in charges in connection with sexual crimes, it is necessary as corroborative evidence to examine the clothing of the person assaulted, and also of the person accused, for the presence of spermatozoa. This is sometimes not an easy matter, since the underclothing of these so assaulted is by its means characterized by its cleanliness, and, indeed, very often bears traces of dirty habits.

As a general rule seminal stains are, when dry, of a greyish-white appearance, and impart a stiffened, starched feeling to the examining finger. That, of course, is a general rule, and it must be remembered that the same description applies to stains of other origin.

Leucorrhoeal discharges have the same characteristics, and are found in like positions on the underclothing. When seminal fluid is shed on a greyish-white cotton material it is very difficult for the naked eye to perceive the stain, which in consequence might be quite easily overlooked. Seminal stains, even when made to the naked eye, have a strong fluorescence when exposed to filtered ultra-violet light. This I am a photograph in

FIG. 1. Seminal stain on cotton fabric.

The photograph shows a rectangular piece of fabric, likely underclothing, with a dark, irregular stain on it. The stain is illuminated by a bright light source, causing it to fluoresce and stand out against the lighter background of the fabric. The photograph is labeled 'Fig. 1' in the top left corner.

ordinary light of a piece of white material from a case of rape. To the naked eye there was no trace of a stain. To the naked eye, however, the stain was apparent to be clear, and it was found to be a seminal stain. The stain was not visible to the naked eye, but it was visible to the naked eye when exposed to filtered ultra-violet light. The stain was not visible to the naked eye, but it was visible to the naked eye when exposed to filtered ultra-violet light.

he attempted. He was a keen and excellent shot, and one's mind goes back to many pleasant Saturdays with him and his son—whose untimely death was so great a blow—on a little shooting near Edinburgh, where there was no keeper and each of the three carried a game-bag, and where the day was often prolonged till the mile to the station had to be covered at a trot! On such days as these his habitual reserve vanished, and no more genial companion could have been desired. In his younger days he was, after W. G. Grace, one of the best amateur batsmen in England. For "W. G." he had a profound admiration, and regarded him as the best batsman who had ever lived. He had an unmitigated contempt for the type of modern batsman who plays the ball with his legs, and in a conversation less than a fortnight before his death reiterated the change in the I.b.w. rule which he had frequently advocated, the details of which, however, are too technical for this *Journal*!

He was a popular teacher of clinical surgery, considerably over a hundred students being often at his clinics. His teaching connexion with the Edinburgh Medical School closed more than twenty years ago, but his students will remember him with gratitude and his colleagues with respect; and to those who had got past his reserve and enjoyed his friendship his death will be a source of real and personal grief.

JOHN STEWART, LL.D., F.R.C.S.Ed.

Formerly Professor of Surgery and Dean of the Medical Faculty,
Dalhousie University

We regret to announce the death, on December 27th, 1933, at Halifax, of the veteran Canadian surgeon Dr. John Stewart, who resigned in 1932 from the post of dean of the faculty of medicine at Dalhousie University. For more than half a century he was the leading figure in the medical life of Nova Scotia.

John Stewart was born in 1847, and, after studying medicine at Dalhousie University, went to Edinburgh, where he graduated M.B. and C.M. in 1877. While a dresser in the surgical wards of the Edinburgh Royal Infirmary he won the regard and confidence of Lister, whose house-surgeon he became and whom he later accompanied to King's College Hospital, London. After a year in London he returned for family reasons to his native Province, where he introduced the principles of the new antiseptic surgery. In 1913, being then professor of surgery at Dalhousie, he received the honorary degree of LL.D. from the University of Edinburgh, and was elected an honorary Fellow of the Royal College of Surgeons of Edinburgh. On the outbreak of war in the following year, being then aged 67, Dr. Stewart volunteered his services in the field and came to Europe as commanding officer of the No. 7 (Dalhousie) Stationary Hospital unit, with the rank of lieutenant-colonel C.A.M.C. On his 70th birthday he was honoured by the King reviewing the unit. In March, 1918, he was appointed consulting surgeon to the Canadian forces in France. His war service was recognized by mentions in dispatches and the award of C.B.E., and McGill University conferred upon him its LL.D. degree *honoris causa*.

On his return to Canada from overseas Dr. Stewart was appointed dean of the Dalhousie Medical Faculty, and the subsequent great progress of the school owed much to his wisdom and experience. He was one of the first Canadian surgeons to be elected a Fellow of the American College of Surgeons. In the summer of 1927, during the Annual Meeting of the British Medical Association in Edinburgh, Dr. Stewart played a prominent part in the latter's centenary celebration, and in 1930, when the Association met in Winnipeg, he took the chair on the occasion of Lord Monmouth's Eastern Oration.

J. A. RAWLINGS, M.R.C.P.Ed.

Consulting Physician, Swansea General Hospital

By the death of Dr. John Adams Rawlings the town of Swansea has lost its best known and most respected citizen. Few, if any, who knew him would disagree with that statement. Though many differed from him in his pronounced and uncompromising opinions on temperance, the observance of the Sabbath, and certain social problems, no honest man could doubt his sincerity, nor fail to admire him for having the courage of his convictions. His long life was devoted with tireless energy to the service of God and man. Physician and lay preacher of the Gospel, town councillor and magistrate, musician and *littérateur*, politician and philanthropist, he took a keen interest in all human affairs that he considered worthy of attention. Frequently engaged in controversy, he sometimes blazed with righteous indignation, but he was always filled with a truly Christian love for his fellow men, and all who had the privilege of knowing him intimately loved him dearly.

John Adams Rawlings was born on May 20th, 1848, at Pickering, Yorkshire, his father being Charles Rawlings, a Wesleyan minister. He was named Adams after his uncle, the Rev. John Hughes Adams, an eminent divine. The family came to Swansea in 1863, when the Rev. Charles Rawlings was appointed superintendent of the circuit. At the early age of 14 J. A. Rawlings was organist to a chapel at Hull, and at 17 he became organist at Wesley Chapel, Swansea. He was fortunate in his musical tutors, one of whom, Herr Catenhausen, had been a pupil of Mendelssohn. He was a student at Guy's Hospital, London, and qualified as M.R.C.S.Eng. and L.S.A. in 1870, and immediately started practice in Swansea. Six years later he became M.R.C.P.Ed. He soon established an extensive practice, and was dearly loved by all his patients, especially by the poor, amongst whom he did much gratuitous work. Dr. Rawlings was a member of the honorary medical staff of the Swansea General Hospital for sixty-three years. He was appointed out-patient medical officer in 1870, honorary physician in 1881, and consulting physician in 1897, an appointment which he held until his death on December 6th, 1933. In addition to his professional duties he took a very active part in the management of the institution.

Dr. Rawlings was a member of the B.M.A., an expresident of the South Wales and Monmouthshire Branch, and a vice-president of the Section of Obstetrics when the Association met at Swansea in 1903. He was not a total abstainer in his earlier years, but soon after starting practice he came under the influence of the late Sir Benjamin Ward Richardson, who so convinced him of the physical, moral, and social evils of alcohol that he became a total abstainer himself and an ardent advocate of temperance reform. He was averse from prescribing alcohol even in illness. During a serious epidemic of typhoid fever at Swansea in 1884, contrary to the then prevailing medical opinion that alcohol was essential in the treatment of typhoid, he refused to allow its administration to a single one of the numerous cases he treated. His results compared favourably with those of his colleagues, who all prescribed alcohol freely. This caused some surprise at that time, but we see nothing remarkable about it nowadays, except that Rawlings had the courage of his convictions to act contrary to accepted medical teaching, although he was only a young country practitioner. With one exception in 1907, I have not attended a case of typhoid since the Boer war, but I gather from my medical colleagues that alcohol is now seldom prescribed in the treatment of this disease.

Dr. Rawlings was first elected to the Swansea Town Council in 1884, and was in office continually for twenty-six years. At one time or another he was a member of all the principal committees. On the formation of the

he published in 1882 an account, "Endemic Haematuria of Hot Climates caused by the presence of *Bilharzia haematobia*," contributed the article in the first edition of Clifford Allbutt's *System of Medicine* (1897), and remained interested in until the end of his life. In 1881 he went out as a doctor in the first Boer war, but otherwise he never engaged in ordinary practice, wrote on strictly medical subjects, or put his name on the *Medical Register*. From 1882 to 1884 he was naturalist in the yacht *Marchesa* exploring Kamschatka, New Guinea, and the Malay Archipelago, and in 1887 worked at zoology in Cyprus. In 1888 he was elected to the lectureship on geography, then established at Cambridge, and lived opposite Pembroke College, of which he was later made an honorary member. After a year he gave up the lectureship, and in 1892 accompanied Sir Charles Euan-Smith on the mission sent by Lord Salisbury to negotiate the terms of a commercial treaty with the Sultan of Morocco. Guillemard, who was general editor of the *Cambridge Geographical Series* from 1896, was the author of many books and papers on geography, travels, and natural history, edited the works of others, and had committed to paper his reminiscences, *The Years that the Locust Hath Eaten*, but did not intend to publish them. His artistic tastes were shown by his collections, especially of pictures and furniture, in the charming Old Mill House on the Trumpington Road, about two miles from the centre of Cambridge, where he had lived since 1898. There with servants who had been with him for over thirty years he lived much in the style and comfort of Victorian days, without the telephone, electric light, central heating, or a motor car. With an old-fashioned courtesy he was a most interesting companion, an original member of the "Arcades," one of the inter-University dining clubs, and naturally had a wide circle of friends. H. R.

ANNIE JACKSON, M.D.

Anæsthetist, Derbyshire Hospital for Women

In her seventy-first year Miss Annie Jackson, M.D., passed away on December 30th, 1933, with little or no warning that her health was impaired. She was born at Garstang in Lancashire in 1863, and was educated at a Quaker school at Scarborough, being brought up in, and remaining a member of, the Society of Friends. It was not until the age of 35 years that she began the study of medicine, when she entered the Medical College for Women at Edinburgh, and obtained the degree of M.B., Ch.B. in 1904. The year following she took the diploma in midwifery in Dublin. After holding the posts of house-physician to the Leith Hospital, and resident medical officer at the Hospital for Women and Children in Edinburgh, she entered private practice at Derby in 1908. She was actively engaged in a busy practice until the day of her death, and her sound knowledge and wise judgement were well known to her medical colleagues. In 1915 she proceeded to the M.D. degree. During the war years many colleagues and patients were indebted to her for a great deal of extra work. Dr. Jackson was always keenly interested in the scientific side of her profession, and although she did not see her way to accept the presidency of the Derby Medical Society, she served on the council and was a regular attendee at the meetings. She was a member of the Panel Committee at the time of her death, and had held office on the Executive Committee of the Division of the British Medical Association. For many years she was honorary medical officer to the Home of Rest, and was a highly skilled anæsthetist to the Derbyshire Hospital for Women. Temperamentally she was more inclined for private than public activities, but she held a position, respected by her medical colleagues and the public, which was uniquely her own.

The death took place, on December 25th, 1933, following an operation, of Dr. C. B. GUNN of Peebles. Born at Edinburgh in 1860, Dr. Gunn took his medical course in the University of Edinburgh, where he graduated M.B., C.M. in 1882. After a period as assistant to a doctor at Newburgh, Fife, Dr. Gunn began practice in Peebles, and was one of the best-known practitioners in the South of Scotland for close on half a century. In addition to a large practice, he was medical officer to the Manor Valley Sanatorium, and held numerous local appointments as certifying factory surgeon, medical officer to the Scottish Education Department, medical referee under the Workmen's Compensation Act, etc. He had a strong literary vein which made him known to a much wider circle than that in which he practised. His father had been on the staff of the *Edinburgh Evening Courier*, and from him Dr. Gunn inherited a strong literary ability. His inclinations lay especially towards the historical and antiquarian side of literature, and his *Books of the Churches of Peebleshire* provides valuable material for students of church history and of social customs in Scotland. This work involved patient investigation for many years, and will probably form his most noteworthy memorial. His *Books of Remembrance of the Town and County of Peebleshire* forms a record of the Peebleshire men who fell in the great war, and was an arduous labour of love. He also published a volume of verse entitled *A Doctor's Thoughts*. His antiquarian interests led him to revive many old Border customs and traditions, among them the annual summer festival of Beltane, and in the restoration of the old Cross Kirk of Peebles he rendered valuable assistance to the Office of Works. His services to the town in which he practised were recognized in 1933, when he was made a Freeman of Peebles. Dr. Gunn is survived by a widow, two sons, and two daughters.

Dr. ALEXANDER PAINE, formerly director of the Research Department of the Cancer Hospital, Fulham Road, S.W., died at his home in Shanklin, Isle of Wight, on December 21st, 1933, aged 67. He began the study of medicine at St. Mary's Hospital with an entrance scholarship in natural science, and graduated M.B., B.S.Lond. in 1893, obtaining the M.D. degree in State Medicine in the following year, and the D.P.H. of the English Conjoint Board shortly afterwards. After serving for a time as assistant pathologist on the staff of the Lister Institute of Preventive Medicine, he was appointed assistant bacteriologist and lecturer on bacteriology at St. Mary's Hospital, a post which he relinquished on becoming director of the Cancer Hospital Research Institute. Dr. Paine was a member of the Pathological Society of Great Britain, and a laureate of the Paris Academy of Medicine.

The death, on December 1st, 1933, of Dr. JOHN NEWSOM LAIRD removed from Macclesfield one of its citizens who had been prominent in municipal and scientific as well as in medical circles. Born in 1875, he received his medical education at Trinity College, Dublin, where at one time he was lecturer in botany and zoology, and a member of the Senate of the University. He graduated M.B., B.Ch., B.A.O. in 1902; the next year he proceeded M.D., and obtained the diplomas of public health and L.M. After holding various appointments at Dublin hospitals he came to England to fill the post of house-surgeon at Bootle Hospital. In 1908 he removed to Macclesfield and commenced general practice. His public appointments included those of medical officer to the Sutton and Rainow districts under the board of guardians, school medical officer under the Borough Education Committee, surgeon to the volunteer fire brigade, medical superintendent of the local branch of the St. John Ambulance Brigade, and during the war, medical examiner of recruits at Stockport. He was also deputy commissioner of medical services in Manchester and heart specialist to the Board, and in 1920 was called by the Ministry of Pensions to superintend five neurological boards in that city. Nearly twelve years ago he was elected to the Town

Council as a Conservative; he subsequently sat as an Independent, and, later, as a Labour member. As chairman of the Municipal Library Committee he was very active in reorganizing the administration of the library and in extending its activities until it became a vital factor in local education. He was at various times a member of the Watch, Health, Salaries, and Finance Committees, and his wife also was a member of the Town Council. Dr. Laird's scientific interests were wide, and included archaeology and pathology. Articles by him were published in the *British Medical Journal*, the *Proceedings of the Pathological Society*, the *Journal of Pathology and Bacteriology*, and in other periodicals. He was a member of the British Medical Association and of the Pathological Society of Great Britain.

Dr. OWEN LANKESTER died suddenly on December 25th, 1933, at his home in Upper Wimpole Street, London, where he had been in general practice for many years. Alfred Owen Lankester, born on October 26th, 1859, was the youngest son of Dr. Edwin Lankester, coroner for Central Middlesex; his eldest brother was Sir E. Ray Lankester, the eminent biologist; and his sister, Miss Fay Lankester, was secretary of the old National Health Society. From St. Paul's School he went to St. Bartholomew's Hospital, where he was one of the founders of the students' amateur dramatic society, and he qualified as M.R.C.S.Eng. in 1884. He then held house appointments at Bart's, at the City of London Chest Hospital, and at the East London Hospital for Children. Before moving to Marylebone he practised for some time in South Hampstead. His honorary appointments included those of surgeon to the St. Monica's Home Hospital for Sick Children at Kilburn, and consulting physician to the East London Nursing Association. Owen Lankester, with his great height and massive build and hearty manner, was an unforgettable figure in the medical world of London and in many social circles. His genuine kindness and shrewd common sense endeared him to all who sought his help, and his mere presence in a sick-room did the patient good. Ever willing to give a hand in a good cause, he will be affectionately remembered far and wide, and not least by those who served with him upon the council of Epsom College.

Medical News

In the Section of Surgery of the Royal Society of Medicine (1, Wimpole Street, W.) on Tuesday next, January 9th, at 8.30 p.m., there will be a discussion on Professor G. E. Gask's presidential address, "Strategy in the Fight against Cancer," a report of which appeared in our issue of November 11th, 1933 (p. 868). The discussion will be opened by Professor Gask, Lord Moynihan, Sir Cuthbert Wallace, and Mr. J. P. Lockhart-Mummery.

A meeting of the Pharmaceutical Society of Great Britain will be held on January 9th, at 8.30 p.m., at 17, Bloomsbury Square, W.C., when Professor I. M. Heilbron, F.R.S., will lecture on isoprene as a fundamental unit in the synthesis of plant products. Modern research work has revealed that there exist in Nature numerous groups of substances which, though apparently unrelated, are in effect all chemically derived from the isoprene unit. A general view of some of the more important members of each class will be given, and it will be shown how, by progressively increasing the number of isoprene units, one can pass from the simple essential oils both to the complex carotinoid pigments and to physiologically active and biochemically important substances such as phytol, vitamin A, squalene, and probably the sterols and bile acids.

At the next meeting of the Illuminating Engineering Society in the hall of the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, S.W., on January 9th, at 6.30 p.m., a paper on portable lamps and their applications, by Mr. A. Cunningham, will be followed by a discussion.

Dr. A. T. Stanton was admitted to the honorary degree of Doctor of Science by the Senate of the University of Toronto on November 10th. Dr. Stanton is chief medical adviser to the Secretary of State for the Colonies, and has held the position of Director of Government Laboratories in the Federated Malay States. He was to have received this degree at the opening of the Banting Institute in 1930, but was unable to be present on that occasion, and it has now been conferred upon him *in absentia*, by special statute of the Senate.

Professor C. H. Best, University of Toronto, will give a course of three lectures, illustrated by lantern slides, on "The Role of the Liver in the Metabolism of Carbohydrate and Fat," at University College, Gower Street, W.C., on January 11th, 15th, and 18th at 5.30 p.m. In his first lecture Professor Best will describe the methods of investigating the role of the liver in the metabolism of carbohydrate and fat; in the second, the liver and carbohydrate metabolism; and in the third, the deposition of fat in the liver. The chair will be occupied at the first lecture by Professor C. A. Lovatt Evans, F.R.S. Admission is free, without ticket.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that a new series of lecture-demonstrations has been arranged to take place at the National Temperance Hospital on the second Saturday of each month at 3 p.m. The first of these lecture-demonstrations will be given by Dr. Leonard Findlay on January 13th, and will deal with children's diseases. Another new series of lecture-demonstrations will be given at the Medical Society of London, 11, Chandos Street, W., every Tuesday afternoon from 2.30 to 4 p.m., by Dr. A. E. Clark-Kennedy. The subject of this series will be "General Medicine: Common Symptoms—their Diagnostic Significance, Pathogenesis, and Treatment." The first will take place on January 16th, and will deal with "Indigestion." Each lecture is to be followed by a discussion or a demonstration of cases. On Tuesday, January 9th, at 8.30 p.m., Mr. R. Lindsay Rea will give a demonstration on the fundus oculi, at the West End Hospital for Nervous Diseases, Gloucester Gate, N.W. Three demonstrations of x-ray films and electrocardiograms will be given at 11, Chandos Street, W., as follows: Tuesday, January 16th, at 8 p.m., Dr. Peter Kerley: x-ray films, "Diseases of the Heart and Lungs." Wednesday, January 17th, at 4.30 p.m., Dr. Kenneth Harris: Electrocardiograms. Thursday, January 18th, at 4.30 p.m., Dr. Kerley: x-ray films, "Diseases of the Gastro-intestinal Tract and Bones." Among the special courses taking place in the near future are: cardiology, at the National Hospital for Diseases of the Heart, January 15th to 27th, and dermatology, at St. John's Hospital, January 29th to February 24th.

The annual congress of the German Society of Climatology will be held in Berlin under the presidency of Professor Vogt of Bad Pyrmont, on January 22nd and 23rd.

The January issue of *The Practitioner* is almost wholly given up to a group of eleven papers on diet. The contributors are Drs. Robert Hutchison (history of dietetics), S. J. Cowell (vitamins in clinical medicine), J. A. Nixon (adequate diets in diabetes mellitus), Anson Clark (diet in urinary infections), Hugh Gainsborough (ketogenic diet), E. C. Dodds (dietary treatment of obesity), A. H. Douthwaite (rheumatic disease), Alan Moncrieff (disease in childhood), S. W. Patterson (diseases of the colon), H. Gardiner-Hill (endocrine deficiency), and Sir James Dundas-Grant (treatment of lupus).

The issue of *Pans Medical* for December 23rd, 1933, which is dedicated to the memory of Emile Roux and Albert Calmette, contains extracts from Roux's classical papers on diphtheria toxin, the first clinical use of diphtheria antitoxin, and antitetanic serum therapy, and from Calmette's papers on anti-venom serum therapy, vaccination by B.C.G., and anti-tuberculous dispensaries. Portraits of Roux and Calmette are inserted in the text, including one of Roux on his deathbed.

Dr. Arthur Lankester of Purley has been placed on the Commission of the Peace for the County of Surrey.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Athology Westcott, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Athology Westcott, London.

MEDICAL SECRETARY, Mediscera Westcott, London.

The Address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*); telephone: 62550 (Dublin), and of the Scottish Office, 7, Drumheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Prophylactic Vaccine against Puerperal Septicaemia

"T. K. K." writes: Could anyone inform me whether the injections of suitable doses of staphylococcus and streptococcus (polyvalent) vaccine with a view to avoiding any possible danger of puerperal septicæmia have ever been given during any period in pregnancy. Is it or is it not possible materially to lower the even small chance of puerperal septicæmia through these injections? What are the best time and the dangers of this procedure?

* We have submitted this inquiry to Dr. Leonard Colebrook (Queen Charlotte's Maternity Hospital), who states: "I am not aware that a polyvalent vaccine of staphylococcus and streptococcus has been employed for the prevention of puerperal fever, and I think inclusion of the staphylococcus would hardly be worth while, inasmuch as there is so little puerperal infection caused by that microbe. Polyvalent vaccines of streptococci alone have been used on a considerable scale in Germany by Jotten and Maroudis, and by Louros in Athens, and also to some extent in America (Lash), and each writer has claimed some advantage from their use as judged by statistical analysis. Personally I do not think the claims are very convincing. My colleague Dr. Hare, of the Bernhard Baron Memorial Research Laboratories, has done a great deal of work in an attempt to prevent vaccination on a more satisfactory basis, but the outlook is not very hopeful because of the multiplicity of streptococcal types causing these infections. It seems that protection against one type is unlikely to protect against others. If preventive inoculation were attempted, it should, I think, be done in the last four weeks of pregnancy, but until we have a more satisfactory scientific basis for it I do not think it worth while. For further references see Maroudis (*Woch. med. Woch.*, 1923, lxx, 727) and Jotten (*Arch. f. Gynäk.*, 1917, cxv, 59).

Medical Book-keeping

"M.B. Ch.B." writes, with reference to Dr. W. H. Rowthorn's note (December 9th, 1933, p. 1102), to inquire when the article on simple methods of book-keeping, by Dr. Rowthorn, appeared in the *British Medical Journal*.

* We read that it was as long ago as January 5th, 1901 (p. 44).

Income Tax

Removal—Double Rent

D. D. D. I. d. to remove from a house rented at £62 10s. per annum owing to the expiration of a lease at March 25th, 1931. To provide an alternative he purchased the lease of another house in October, 1932, and commenced occupation thereof in January 28th, 1933. The new premises are rated at £85 per annum net, and there is a ground rent of £20. Can he deduct the rent of both premises from the date on which the second house was

purchased? Both houses are used exclusively for professional purposes.

* It was decided fairly recently that a company which vacated some premises before the lease expired was entitled to deduct the rent paid for the subsequent period though they were not in occupation (Commissioners of Inland Revenue v. The Falkirk Iron Co., Ltd.). That decision seems to cover the deduction of the rent of the old premises from January 28th to March 25th, 1933. The position with regard to the new premises is somewhat different. "D. D." is entitled to treat the amount on which he pays income tax under Schedule A (probably £85 or thereabouts) as if it were rent paid by him; but presumably no tax was charged on "D. D.'s" ownership of the lease until he came into occupation on January 28th, so no right of deduction for prior periods would arise. The ground rent is not a legal deduction, because "D. D." is recompensed for the tax on it by deducting the standard rate tax from his payments as and when he makes them.

LETTERS, NOTES, ETC.

Herpes Generalisatus

Dr. J. NEWBURY FERGUSSON (York) writes, with reference to the note by Professor J. A. Nixon published last week: I have seen two cases of this interesting condition in which a rash like that of chicken-pox appears in the course of an attack of herpes zoster. The first, of which I have no details, occurred in a female aged 46, whom I saw with a colleague, and the second in a patient of my own, a boy of 14. In the latter the "chicken-pox" showed on the fourth day after the herpes, and the illness was fairly severe for some days. It would appear that the condition is not confined to the elderly, as Professor Nixon's series of cases would seem to suggest. It is briefly referred to in "Osler," and ought to be better known.

Driving in Fog

For the guidance of those driving motor vehicles at night and in foggy weather the Automobile Association, with the co-operation of the Postmaster-General, has erected over 2,000 reflex disks on telegraph poles along important main roads. These disks, together with the familiar safety posts, reflect the light from head-lamps of vehicles by showing a red light when mounted on the near-side of the road, and a white light when on the off-side: thus they clearly indicate a safe course for night traffic. Since by far the greatest number of lights which motorists see on the open road after dark and in fog are the red rear-lamps and white head-lamps of other vehicles, the A.A. suggests this simple rule of the road for night driving: "Pass to the right of a red light and to the left of a white light." A number of highway authorities have extended this principle to cover the lighting of temporary road obstructions, but uniformly throughout the country is needed. Pulling up on the off-side of the road after dark is frequently a source of danger, as the side and rear lights cause confusion, particularly in foggy or "dirty" weather. Motorists are urged to avoid this practice, which is deprecated in the Highway Code.

Corrigendum

In the fourth line of Dr. D. F. Anderson's note on heartburn in pregnancy in last week's issue (p. 1231), "hyperchlorhydria," through a misprint, appeared instead of "hypochlorhydria."

Two x-ray film changes are announced by Kodak Limited. The "duplized" film is now supplied on a safety (cellulose acetate) base at the same prices as on the standard (nitrate) base. The other new feature is the introduction of a blue base for Kodak safety x-ray film.

The Warner calendar diary of medical history for 1934 is now being distributed to those members of the profession who have asked for a copy. Messrs. William K. Warner and Co., Ltd. (300, Gray's Inn Road, W.C.1) inform us that a further limited number is available for distribution to doctors who apply to them.

Vacancies

Notifications of officers vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 44, 45, 46, 47, 48, and 49 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 7.

British Medical Association Lecture

ON

THE TREATMENT OF CARDIAC CASES*

BY

MAURICE A. CASSIDY, C.B., M.D., F.R.C.P.

SENIOR PHYSICIAN TO ST. THOMAS'S HOSPITAL

I have often noticed that when I am honoured by an invitation to address a meeting such as this, the secretary suggests as a suitable topic "modern methods in the diagnosis," or "modern methods in the treatment," of whatever pathological state happens to be specially to the fore in the medical press at the time. Now I do not for one moment wish to criticize this desire to hear about recent developments—they are not always advances—in our art, for it is as admirable to be progressive as it is reprehensible to be reactionary. But in our efforts to keep in the van of progress there is a risk of travelling too far from the base of assured facts, so that we may find ourselves, for instance, dosing our hypertensive patients with the latest muscle or pancreatic extract, so persuasively introduced to us by its enthusiastic manufacturers, rather than giving them humdrum advice as to regime, from which, in the end, they are more likely to benefit.

I have purposely chosen as my text "the treatment of cardiac cases" rather than "the treatment of cardiac disease," because a very considerable proportion of cardiac cases have, as you know, no cardiac disease. By a "cardiac case" I mean a patient whose symptoms, such as shortness of breath, palpitations, or precordial pain, suggest to him, and possibly to his doctor, that the heart is at fault. Before we attempt to treat such a case it is essential that we establish as accurate a diagnosis as we can, and this diagnosis should be a comprehensive one, embracing, if possible, aetiology, morbid anatomy, and disturbance of function. For example, we should not be satisfied with a diagnosis of, say, mitral stenosis, but should aim at describing such a condition as a case of rheumatic heart disease with mitral stenosis and, it may be, auricular fibrillation, with or without congestive failure.

It may interest you to study the figures of an aetiological classification of cardiac cases as seen in consulting cardiologist practice. They are as follows:

843 Cardiac Cases (private practice):			
Neuropathic	29.5 per cent
591 Cases of Organic Heart Disease:			
Congenital	3.0 "
Infective	11.0 "
Rheumatic	5.6 "
Syphilitic	1.5 "
Endocarditis (acute or subacute)	0.9 "
Various	3.0 "
Toxic	8.0 "
Thyroid	5.6 "
Alcoholic	1.5 "
Various	1.5 "
Degenerative	62.9 "
Hypertensive	31.3 "
Decrescent	31.6 "
Respiratory	4.0 "
Doubtful and unclassified	10.0 "

I am sure you will be surprised at the relative infrequency of valvular disease, the incidence of which is only 5.6 per cent., or about the same as that of the thyrotoxic heart. It will be seen that nearly one-third of the patients sent to the cardiologist have, so far as he can ascertain, no organic cardiovascular disease, and that there is an overwhelming preponderance of the hypertensive and decrescent cases (by decrescent cases I mean those in which there is believed to be myocardial degenerative change, presumably secondary to coronary sclerosis, and not attended or preceded by hypertension).

To the average medical man I think it is still true that "heart disease" is almost synonymous with valvular disease and murmurs. This is not surprising, for the bulk of the cardiac cases which he sees in his student days have valvular disease, and most of the pages of his textbooks are devoted to valvular disease, pericarditis, and thoracic aneurysm, with perhaps one skimpy chapter giving a very inadequate account of the all-important hypertensive and decrescent cases. Even that valuable journal *Heart*, quite rightly the pride of English cardiology, is not without sin in this respect, for not long ago there appeared in it a contribution of fundamental importance by R. T. Grant entitled "After-histories for Ten Years of a Thousand Men Suffering from Heart Disease" (vol. xvi, p. 275). This paper is invaluable as a store of statistical evidence as to the prognosis in various forms of valvular disease, and I advise you all to read it. But unfortunately it gives an entirely erroneous view of the relative incidence of the various aetiological varieties of cardiovascular disease as seen in ordinary practice, based as it is on a selected group of the population—namely, war pensioners—in whom, for very obvious reasons, valvular disease predominated.

Now a word or two as to the treatment of cardiac cases in general. I have a conviction that, as a profession, we tend to treat these patients with an excess of caution, erring in the direction of too much rest, and unduly limiting activities. Very rarely do I see cases in which harm has been done by a doctor encouraging his patient to overexert himself; whereas I constantly see patients on whom undue restrictions have been enjoined, and in whom, as a result, it is sometimes very difficult to restore confidence in the heart's capacity for effort. We all know that prolonged rest is essential after any acute infection of the heart, and especially if this infection is rheumatic. So, also, great caution must be enjoined during convalescence from diphtheria, even though there may have been no obvious manifestations of cardiac damage during the acute stage of the illness. Though prolonged rest in bed is rarely necessary during convalescence from acute tonsillitis or influenza, violent effort should never be allowed too soon after these infections. School doctors should impress on house-masters and matrons the importance of not allowing a boy to run races or play games during convalescence from such infections, even when apparently trivial. The few instances that have come to my notice in which harm has been done by exercises have been where a boy has been allowed to race, or to play in an important match, the day after some mild or brief febrile illness—perhaps one not considered of sufficient importance to be reported to the school doctor.

THE "SCHOOLBOY'S HEART"

This leads me to say a word or two about that perhaps most difficult of all cardiac conditions from the doctor's point of view—the "schoolboy's heart." You are all familiar with this picture; usually a rapidly growing boy, often the son of over-anxious parents, and sometimes a boy who is not altogether averse from being excused from games. He complains of palpitations, and possibly of apical pains, and says he gets more easily "windy" than other boys. The apex beat is perhaps forcible and diffuse, and is felt in, or even outside, the nipple line. The heart rate may be rapid, and accelerates unduly on effort or on emotion. There is often a systolic murmur, and in most cases the symptoms date from the discovery of this murmur, generally during a routine examination in the course of some febrile illness. The boy is brought to you by his parents, who are usually anxious that he should be excused from games. The decision in such a case is often a difficult and an exceedingly important one. We must be very careful not to

* Delivered to the West Somerset Division, November 3rd, 1933.

attach a cardiac label to such a boy at a very impressionable age unless we are quite certain that his heart is in fact an unhealthy one; and we must not run the risk of ruining his school, and probably also his after life, by imposing unnecessary restrictions on him. If there is a definite history of recent rheumatism, or if there is conclusive evidence of valvular disease, or if the heart is without a doubt enlarged, we have no option but to forbid games. But we must not pay any attention to cardio-respiratory, or to so-called haemic, murmurs, and we must remember that many boys have an apex beat in, or even outside, the nipple line without any cardiac enlargement. X-ray examination is of great assistance in these doubtful cases, because it is the only means of ascertaining the size and, even more important, the shape of the heart. My usual practice is to allow games under the supervision of the school doctor, possibly forbidding races, rope-climbing, etc., for a time. I have never heard of any harm resulting, and I am quite certain that the boys' parents would not keep me in ignorance of any evil consequence of my advice! Most of these cases are akin to the "soldier's heart" or the "effort syndrome" of Lewis, and the more you rest them the worse they become, and the more difficult they are to cure once you have finally decided that there is no organic heart disease.

CARDIAC NEUROSES

Let us now discuss the treatment of the cardiac neuroses, which, as I said before, constitute nearly a third of the cases sent to the cardiologist. Here treatment may almost be summed up in a single word—reassurance. But the reassurance must be emphatic and without reservation. It is no use telling these patients that "the heart is a little flabby, but there is nothing seriously wrong," or that "there is a slight murmur, of no great importance." It should always be remembered that in the lay mind anything amiss with the heart, however slight, conjures up future, or even present, possibilities of sudden death, and that it is fear which is at the root of their symptoms. Once we have satisfied ourselves, after careful investigations, including, if possible, electrocardiographic and x-ray investigations (for these help to carry conviction to the patient as well as to ourselves), that the heart is healthy, it is our duty to assure the patient that there is nothing whatever wrong with his heart, and that no restrictions of any sort are necessary. In the case of a patient who has been reduced to a state of cardiac invalidism it may not be politic, or indeed possible, to remove all restrictions at once, but even in such a case we should aim at a return to normal life and full physical effort at the earliest possible date. Massage, passive movements, and, later, graduated exercises may be useful here in the early stages of physical re-education.

Drugs play a very subsidiary part in the treatment of these cases, though a short course of bromide or luminal may be helpful. Digitalis is usually contraindicated; it seldom has any beneficial effect on a nervous tachycardia, and the very fact that digitalis is prescribed is apt to foster the patient's conviction that his heart is diseased.

I am fully alive to the fact that in a few cases the doctor runs a certain risk to his reputation by giving such advice. This is especially true in the case of those nervous patients without any physical signs of organic disease, whose history is suggestive, but not conclusive, of angina pectoris. Even here, I think, one is usually justified in the patient's interests in coming down firmly on the instructional side of the diagnostic fence, and in taking an entirely optimistic view of the future to the patient, even though one may have some personal reservations as to the diagnosis. Undoubtedly we take a certain amount of risk by telling such a patient that there

is nothing wrong with his heart, and no need for any restrictions. But it is the only means of curing the patient, who never knows the risk we run in effecting his cure.

ORGANIC CARDIOVASCULAR DISEASE

I have not left myself much time in which to discuss the treatment of organic heart disease. Even here the psychological aspect of the problem must not be disregarded. We must remember that associated with any organic disease there is often a very considerable element of anxiety state. A patient suffering from mitral stenosis, for example, knowing that her heart is diseased, may suffer from precordial pain, from palpitations, and even from dyspnoea, all of purely psychological origin and not directly attributable to the undoubted organic heart lesion. So also an apprehensive man who suffers from angina pectoris due to coronary arteriosclerosis may, through sheer funk, drift into such a state of vasomotor irritability that anginal attacks are induced on the slightest exertion or emotional upset—another example of a functional superstructure on an organic basis. Clearly, then, psychotherapy in the form of reassurance and explanations as to the genesis of symptoms must play an important part in the therapy even of organic heart disease, though this aspect of the treatment is only too often neglected.

Another common mistake is the assumption that all organic heart disease must *ipso facto* produce symptoms and require treatment. I need hardly remind you that this is not true. We all know that valvular disease is often compatible with a normal quiet life, producing no symptoms at all so long as the individual is fortunate enough to be unaware of its existence. For a few years after the war our hospital out-patient departments were thronged with men suffering from valvular disease, real or imaginary, and full of symptoms. Their murmurs had been discovered by medical boards in the Army, they had been "pensioned out," and had suffered from palpitations, precordial pains, etc., ever since. Now, fifteen years after the war, valvular disease has once more become relatively infrequent in the out-patient departments. The subjects of it are, for the most part, at work, symptomless and blissfully unconscious of any disability.

It behoves us, therefore, when we discover the existence of valvular disease, to determine to what extent, if at all, the efficiency of the heart as a pump is impaired, and whether any of the symptoms complained of are due to the organic lesion or to an added anxiety state. We must inquire carefully whether there is any evidence of undue dyspnoea on effort, and if there is, we must note the degree of effort that is required to produce such distress. We must also ascertain whether the patient is able to sleep well with not more than two pillows, and without attacks of nocturnal dyspnoea and wheezing. We look for early signs of congestive failure, engorgement of the neck veins, oedema of the bases of the lungs, and a tender enlargement of the liver. We inquire as to oedema of the ankles at the end of the day.

If a patient is able to carry on the ordinary routine of his life without undue dyspnoea, if he sleeps well, and if there is no evidence of early congestive failure, we can assure him that his valvular lesion is no serious disability, and is compatible with many years of average health. He must not attempt any exertion which makes him badly out of breath, and he must be strictly moderate in food, alcohol, and tobacco. He must lead as normal a life as he can within his limits, and the less medical treatment he has the better for him, although he would be wise to undergo periodical medical examinations, and he must send for his doctor at once if he develops a febrile illness.

INDICATIONS FOR DIGITALIS AND QUINIDINE

When, on the other hand, there is evidence of early congestive failure, or a history of paroxysmal nocturnal dyspnoea, strict rest in bed must be enforced until such signs or symptoms have disappeared, after which cautious experiments must be made to determine how much exercise, and how long a day, can be allowed with safety. It is unnecessary for me to detail the treatment of advanced congestive failure, with oedema and ascites. I need only remind you that if auricular fibrillation is present digitalis must be given in adequate dosage; in other words, it must be pushed until signs of intolerance appear, such as nausea, vomiting, or diarrhoea, or until the ventricular rate by auscultation falls to about 70. It must be stopped at once when the rate falls below 60, and also if digitalis coupling appears. I still see patients who are suffering from auricular fibrillation with gross congestive failure being treated with such an inadequate dose as ten or even five minims of the tincture three times a day.

When dropsy persists in spite of adequate digitalization, or in the absence of fibrillation, when digitalis is not nearly so effective, the mercurial diuretics are often successful. Salyrgan is safer than novasurol, and novuril, I think, safer and better than either; but any one of these three preparations may be successful where the others have failed.

Venesection, and, in obstinate cases of dropsy, the insertion of Southey's tubes, are not, in my experience, employed quite as often and as early as they should be.

For the relief of paroxysmal nocturnal dyspnoea no drug is comparable with morphine, which is too often withheld; not only does it relieve the distressing symptoms, but after a few good nights so obtained an astonishing improvement in the patient's general condition may be observed.

Quinidine is a drug which is used at times somewhat rashly, and in unsuitable cases. It may be helpful, therefore, to say a few words as to the indications for quinidine therapy. Quinidine is perhaps most valuable in the prophylactic treatment of auricular fibrillation. Paroxysms of fibrillation sometimes occur during the early stages of myocardial degeneration; as time goes on these paroxysms become more frequent and more prolonged, until, eventually, fibrillation becomes continuous, with a considerable resultant disability. By a daily dose of three or five grains of quinidine it is often possible to prevent such paroxysms, and to postpone for some years the advent of established fibrillation. What are the indications for quinidine therapy once fibrillation has become established? They are: a short history of fibrillation; absence of valvular disease—and especially of mitral stenosis; absence of any evidence of congestive failure; and an electrocardiograph which shows no evidence of gross myocardial change apart from the fibrillation.

In fibrillation associated with a toxic goitre also quinidine is often successful, though in most cases thyroidectomy is necessary sooner or later if normal rhythm is to be maintained. May I take this opportunity of reminding you of the importance of considering the possibility of a thyrotoxicosis when investigating a case of auricular fibrillation of obscure aetiology? It does not appear to be generally recognized that quite a small, and not at all an obvious, adenoma of the thyroid gland may cause auricular fibrillation, and may do so with very little evidence of other thyrotoxicosis; for instance, there may be no obvious proptosis, no tremor and no sweating, and the basal metabolic rate may be little, if at all, increased. Nevertheless, surgical treatment of such cases is usually followed by restoration of normal rhythm, so that I need not further emphasize the importance of early recognition of this type of case.

THE MINERAL BASIS OF LIFE*

BY

J. H. SHELDON, M.D., F.R.C.P.

HONORARY PHYSICIAN TO THE ROYAL HOSPITAL, WOLVERHAMPTON, AND
HONORARY PHYSICIAN TO THE GUEST HOSPITAL, DUDLEY

Most medical men were brought up on the teaching that, in spite of the great variety of the elemental constituents of the inorganic world, the living body was extremely selective in its needs, and made use of only a few of these elements. For many years the occasional presence of traces of others has been reported by various workers, but their observations have attracted little interest, and it was generally thought that they were accidental contaminants. It is now recognized that the original list of the constituents of protoplasm (C, H, O, N, S, P, Na, Ca, K, Mg, Cl, I, Fe) must be widely extended. In the first place, new methods of research, both chemical and physical, have shown that many other elements, particularly metallic ones, are commonly present in animals and plants. Secondly, there are certain observations which tend to show that in the course of evolution nature has been making experiments in the attempt to find the most suitable metal for certain functions, particularly for use in the respiratory pigments.

The most important evidence that the original list is too exclusive, however, is the successful demonstration by the Wisconsin school, led by Hart, Steenbock, and Elvehjem, of the essential role of copper in the formation of haemoglobin. Their work, which has now become classical, indicates that the presence of copper can no longer be regarded as accidental—the metal, though present only in "traces," has a definite function in which it cannot be replaced by any other element. It is this work in particular, and also the demonstration of the necessity of certain other elements for plant life, that has stimulated a search for those that may be found to occur in living tissues, and for the functions that they may perform. It may be said at once that the former line of work is much the easier, and that in consequence our knowledge of it is in a more advanced state. The pioneer work of Bertrand in Paris, and of Ramage in Norwich, has contributed greatly to our knowledge. The discovery of the actual function in cell metabolism of the mineral constituents presents a problem that does not often yield readily to frontal attack, and depends on the general advance of biochemical knowledge. This may be seen in the case of magnesium, where the recent investigations on the processes of fermentation and of muscular contraction have shown that this element possesses a specific action on the phosphatase enzymes. A review of the mineral basis of life must therefore at the present time largely concern itself with a review of the various elements which have been found to occur with any constancy in living tissues.

1. The Halogens

The presence of chlorine in the body is well known, and its importance needs no stressing. The importance of iodine as a constituent of the thyroid secretion is also well known, but recent work indicates that the role of this element is not confined to its participation in the structure of thyroxine, and that it has other unsuspected activities. Iodine is a constant constituent of the blood in an amount that is generally agreed to be of the order of 12 γ per 100 c.cm. (1 γ = 1/1,000 mg.), the total amount in the blood being, therefore, less than one milligram.¹ The amount is raised in hyperthyroidism and lowered in hypothyroidism, and indeed the level of the blood iodine reflects the functional state of the

* Presidential address delivered to the Staffordshire Branch of the British Medical Association, October, 1933.

thyroid in the same way that the blood sugar reflects that of the islet tissue, or the blood calcium that of the parathyroids. An interesting recent discovery has shown that while all parts of the brain contain iodine, the greatest amount is found in the region of the tuber cinereum, which contains twice as much as the cerebrum and three times as much as the cerebellum.² This fact gains in significance when it is remembered that the tuber lies just above the pituitary, and that in this region is undoubtedly concentrated the control of many of the metabolic processes which are affected by the pituitary. Iodine would therefore appear to be concerned in the control of metabolism through the diencephalon as well as through the thyroid.

The presence of bromine in the normal body has not been recognized for so long, but there appears to be no doubt that bromine must be classed with iodine and chlorine as an element which is constantly present. In one investigation it was found in the blood in each of 150 cases—in an amount from 0.8 mg. to 1 mg. per 100 c.c.m.³ A very curious feature, originally described by Zondek and Bier⁴ and since confirmed by the original authors and by three separate groups of workers,^{5,6,7} is that the blood bromine is lowered to half its normal figure in cases of manic-depressive psychosis, and only returns to normal values with an improvement in the clinical condition. The blood bromine also appears to vary with menstruation. In the tissues, bromine is found in greatest amount in the pituitary gland, especially in the anterior lobe, where it occurs in a concentration seven to ten times greater than in any other organ. It shows an extraordinary variation with age; after 45 the amount begins to fall, and in persons who reach the age of 75 the bromine is either present in the merest traces or is not detectable at all.⁸ These facts are intriguing, and strongly suggest that bromine plays an important part in the body economy. It is curious that bromine should be so concentrated in the pituitary, while iodine is concentrated in the tuberal region just above. Bromine also appears to be a normal constituent of plants, the amount varying between 0.17 mg. and 2 mg. per 100 grams of dry matter.

In the case of fluorine, the remaining member of the halogen series, the picture is different, for there is no decisive evidence that it is a normal constituent of either the animal or plant kingdom, although it has been found on many occasions, and is said to occur in blood and milk.⁹ While it is still an open question as to whether fluorine has any physiological function, there can be no question as to its pathological importance, especially with regard to the teeth. In rats, feeding with fluorine produces a characteristic overgrowth of the upper incisors, accompanied by a defective development of the enamel, leading to a mottled appearance.¹⁰ This is of great practical importance, for in Algeria it has been shown that a widespread illness known as "darmous," which affects animals as well as man, and which is characterized by a general cachexia in addition to dental dystrophy, is due to the high fluorine content of the water supply, which is derived from wells containing "natural phosphate." The mottled appearance of the teeth is caused by spots of the patches, which are areas of defective enamel formation. In 1924 an outbreak of mottled teeth had been reported for the first time in the locality of Moulins, the use of water from new deep wells, the previous water supply having been from shallow wells.¹¹ It is a recent study of English children in a similar condition of the teeth to those in children from Moulins, Essex, has been found to be associated with a high fluorine content of the water supply.¹² It would appear that fluorine is not a normal constituent of the body, but is not a toxic substance in the same way as the other halogens.

2. Boron

It is generally agreed that boron is universally present in the plant kingdom, and that it is essential to normal plant growth.¹³ The optimum concentration for plant growth is of the order of 1 part per million. Its effects appear to vary in different species, but in leguminous plants, such as the broad bean, the presence of these minute quantities of boron are essential for the proper formation of the root nodules. In the absence of boron the structure of the nodule becomes defective, and the nitrogen-producing bacteria lose their symbiotic habits and become parasitic, invading the host.¹⁴ Nitrogen assimilation is consequently much below normal. It also plays a part in calcium metabolism, since in the absence of boron the broad bean cannot assimilate calcium. There is no certain knowledge of either its presence or function in the animal kingdom, though Bertrand and Agulhon claim to have demonstrated it in blood,¹⁵ and it has also been demonstrated in human milk.¹⁶

3. Silicon

The pathological activity of silica, especially in regard to the industrial importance of its inhalation as silica dust, is well known. In minute quantities this element is a constant constituent of the plant kingdom, particularly in the stems of cereals. It is concerned with the metabolism of phosphorus. The amount of phosphoric acid taken up by the plant is proportional to the amount of water-soluble silicate in the soil.¹⁷ It is said to be of constant occurrence in human blood,¹⁸ averaging 16 mg. of SiO₂ per 100 c.c.m., and a combination of silica and carbohydrate has been demonstrated in gelatin, ox blood, and human urine.¹⁹ The most striking evidence of the widespread occurrence of silica in human tissues is the spectrographic demonstration of its presence in the aqueous humour of the eye.²⁰ It is quite impossible to say whether it has a function, but its presence is not unexpected, in view of its constancy in plants and therefore in food. The silica content of bread varies up to 3.2 mg. per 100 grams (dry), being greater in whole-meal bread than in fine milled bread.²¹

4. Alkali Metals (Na, K, Li, Rb, Cs)

The distribution of the alkali metals is peculiar. Sodium and potassium are, of course, essential to life and of universal occurrence. The remaining elements show great variation. Lithium is sometimes found in human²² and in invertebrate tissues,²³ but only spasmodically. It is constantly present, however, in marine animals, and in plankton it usually reaches a considerable concentration. So far as land animals are concerned, it appears likely that the metal is taken up by the tissues when present, but there is nothing to suggest that it has any definite function. Caesium offers a sharp contrast in that it is almost universally absent from animal tissues, although feeding experiments show quite definitely that it is readily absorbed. Caesium is a constituent of sea-water, and has been detected in plant ash²⁴ and in oyster shells.

Rubidium is of much more frequent occurrence. It occurs in plants,²⁵ and appears to be especially important in the fungi,²⁶ some of which contain quite remarkable amounts, reaching at times 0.2 per cent. (dry), which compares with an average figure for human beings of about 0.003 per cent. It is also of widespread occurrence in the animal world. In invertebrates the analysis of English snails and earthworms showed considerable differences with regard to locality, since rubidium was present in specimens from Liverpool and Marlborough, and absent from specimens obtained in Cambridge and London.²⁷

* It is not known whether this finding has any application to the question of metabolic pathology.

This suggests that the element resembles lithium in being absorbed by protoplasm in proportion to its availability. In human beings, on the other hand, rubidium is found much more frequently. We found that it was almost invariably present in adult human tissues,²⁹ while in an examination of 111 foetal and infant livers the metal was present in every instance but one.²³ A curious feature was that the amount of rubidium was much greater than the average in those dying from congenital pyloric stenosis. Rubidium is present in human milk,^{26, 27} which suggests that it may be of physiological importance. The amount in the liver rises slightly during the nursing period, and this, together with its height in pyloric stenosis, suggests that it may be of importance in growth, possibly of the muscles. This suggestion derives some support from one particular fact—namely, that in wheat, barley, and oats—and ratio Rb : K is always higher in the growing point than in other parts of the straw.

5. Alkaline Earths (Be, Ca, Ba, Sr, Mg)

Of these metals, calcium and magnesium are well known as constant and essential constituents of protoplasm. Magnesium occupies a position of particular importance in the plant world owing to the fact that it enters into the composition of chlorophyll. Recent work has confirmed the importance of magnesium. Krause, Orent, and McCollum³¹ found that animals deprived of magnesium died in a short time, showing marked vasodilatation and tetany. Cramer³² discovered the very intriguing fact that rats fed on a diet deficient in magnesium developed clear evidence of renal damage. Beryllium does not appear to have been described in living tissues, but it is important in that it is capable of producing a severe rickets when fed to animals. Strontium occurs spasmodically in both animals and plants. We found it in the tissues of a few-weeks human foetus, so that it is able to pass the placenta,³⁰ and it has also been found in the human eye.¹⁴ Snails appear to have a predilection for strontium when it is available,²¹ but show the same type of variation with locality that is found with rubidium. All the evidence goes to suggest that strontium is readily taken up by tissues when it is available, but the irregular character of its distribution does not suggest that it has any definite function. Barium is found much less frequently than strontium, occurring only spasmodically and in minute traces. The solitary exception to this is in the eyes of cattle, which regularly contain barium in the choroid, in amounts which increase with age. Concurrently with this increase in barium there is a decrease in the amount of copper and certain other elements in the choroid. This observation was confirmed for cattle coming from Wolverhampton and Norwich, but it does not occur in any other animal that we have been able to investigate.³⁰ The significance of this observation is entirely obscure.

6. Copper

Copper is so universally present in both animal and plant kingdoms that it may be accepted as an element necessary to life. No extensive investigations of tissues making use of modern methods have failed to demonstrate the presence of copper. In plants it occurs in all parts, but is found in greater concentration in leaves and fruit than in the roots; and it is especially concentrated in the fruit. (This is true also of most of the heavy metals which occur in plants; as they pass up the stem from the root they appear finally to be concentrated in the fruit.)²⁴ In animals the greatest amounts of copper are found in the liver, though it is present in all tissues. It occurs in greater concentration in the blood plasma than in the cells, and the greater part of the serum

copper appears to be in combination with the proteins. The level of the serum copper is normally about 80 to 90 γ per 100 c.cm. It is raised in certain types of anaemia, in pregnancy, and probably in malignant disease,³¹ though much more work is necessary on these points. It is a curious fact that the alterations in the mineral content of the blood tend to be of a similar nature in both pregnancy and carcinoma.

Of the many functions undoubtedly exercised by copper in the body, only one is known with any certainty—its essential role in the formation of haemoglobin. This has been conclusively proved by Hart and his co-workers at Wisconsin in the case of the chicken, pig, rat, and mouse, and their work has also made it clear that no other metal can replace copper in this particular function.³² There is no rigid experimental proof that the same is true of man, but the collateral evidence leaves little doubt that this is the case. The most important evidence is the fact that the human infant is provided with a store of copper in the liver, which is mainly laid down during the last months of foetal life. This store is rapidly used up during the nursing period, and the very close similarity in this respect of the curves for copper and iron strongly suggests that they are both being used for similar purposes. This initial store appears to be true of all animals the young of which depend for a time on a milk diet alone, though it is not the case with animals, such as the guinea-pig, in which a milk diet is supplemented by other food from birth. It should be pointed out that although the copper content of human milk is low it is higher than cow's milk, and that all milk appears to have the power of abstracting copper from metal containers. Thus there is a significant rise in the copper content of cow's milk which has been submitted to pasteurization in contact with copper.³³ The participation of copper in the formation of haemoglobin is, however, not the whole story, for one generally finds that copper is richer in young growing tissues than in adult ones—thus we found a distinct difference between the copper content of teeth of the first and second dentitions.²⁹ This suggests that copper may be directly concerned in the processes of growth. In this connexion it is interesting to note that in carcinoma cells the amount of copper is usually low although the blood copper may be high. There can be little doubt that this element has many important functions, and the demonstration of a copper-porphyrin compound in cells³⁴ suggests that, like iron, it may be concerned in the processes of intracellular oxidation. The pigment of the tail-feather of the toucan is due to the presence of a copper-porphyrin compound.

It has also been suggested that copper acts in the body in relation with the vitamin B complex.³² The available evidence suggests that in vertebrates, at any rate, iron and copper have closely related physiological functions. Copper appears to play a more predominant part in invertebrates. It is a well-known fact that in certain arthropods and molluscs the respiratory pigment of the blood (haemocyanin) contains copper in place of iron. One of the highest copper values in the whole of the animal kingdom is found in the wall of the ink-sac of the octopus,³⁵ where the enormous figure of 914 mg. per kilogram of dry tissue may be found. The ink itself contains only minimal traces of copper, being of melanin nature, and this extraordinary finding suggests that copper may have unsuspected points of contact with the metabolism of the melanins.

From a pathological point of view, copper is of chief interest in relation to cirrhosis of the liver, and to haemochromatosis. A well-known explanation of haemochromatosis is that advanced by Mallory,³⁷ who thought

that the disease was the result of chronic copper poisoning. Although for many reasons this theory is untenable, the fact remains that in haemochromatosis the tissues, especially the liver, do appear to have a higher copper content than normal.²² High copper values are also common in ordinary cirrhosis of the liver (the figures may equal those found before birth); they are, as far as I know, the only conditions in which these high copper figures are found. It would be tempting to conclude that in each case the copper is playing an operative part in the production of the disease, especially in view of the successful experimental production of cirrhosis by the use of heavy metals, but the available evidence strongly suggests that in both instances the high copper content is a secondary phenomenon. The most important evidence lies in the fact that these high values are not universal, and there is clear evidence that cirrhosis can develop with normal copper values. In one example of congenital cirrhosis of the liver which we were fortunate enough to obtain for examination,²³ the copper values were very much less than the normal for that age.

7. Manganese

Manganese is widely spread through both animal and plant kingdoms, and there is abundant evidence that this element is essential for life. The presence of manganese in plants is said to have been discovered by Scheele as far back as 1755. It has been proved to be necessary for the growth of plants,²⁴ and it seems to bear some relation to the formation of chlorophyll, for it is found in leaves in amounts proportional to their greenness.²⁵ Generally speaking, it is far more abundant in those parts in which active chemical changes occur—such as roots and leaves and especially in the reproductive organs—than in the passive parts such as the stem. This has recently been confirmed for Australian plants in a very careful study by Bishop.²⁶ Manganese resembles boron in that, though essential for growth, too high a concentration leads to toxic changes; and a very curious feature described by Bishop is that calcium has the power of protecting the plant from this toxic action. In animal tissues manganese is widely spread, but occurs in greatest quantity in the liver and pancreas, while in some individuals we have found the suprarenals to contain large amounts. Different species show a considerable variation in the manganese content of their tissues. Herbivorous animals such as the guinea-pig usually have high values, while in comparison man has low values.²⁷

Manganese is found in the blood, and so far as our limited observations go²⁸ it occurs in the serum but not in the cells. It is widely spread in invertebrates, but, as with other metals, the amount tends to show considerable variation with locality. Thus snails from some regions possess enormous amounts.²⁹ In human beings there is no pre-natal store of the metal, and the values, beyond showing a slight drop during the nursing period, tend to follow a remarkably constant course throughout life. This suggests that manganese has no particular functions during development, but against this there is the very remarkable fact that meconium contains a quite remarkable amount of manganese,³⁰ and there is no doubt that the human foetus is normally provided by the mother with an excess of this metal. In view of the general tendency to ascribe to manganese a function as a stimulant of oxidative processes, it is tempting to ascribe the marked temporary provision of this metal for the foetus to the relative oxygen deficiency of fetal blood due to the fact that the placenta is not as good a respirer as the lungs.

A series of feeding experiments on animals conducted by Gross and M. G. Clark³¹ have indicated that manganese

is in some way essential to the reproductive processes. Briefly, an absence of sufficient manganese in the diet leads to: (1) an atrophy of the testes in the male, and (2) in the female to a peculiar alteration of the maternal instinct so that she fails to suckle her young. In vertebrate animals manganese has apparently no function in the formation of haemoglobin, though in invertebrates a remarkable fact which should not escape notice is that the Lamellibranch *Pinna squamosa* contains a respiratory pigment very similar in constitution to haemocyanin, except that it has manganese in place of copper. This appears to be a solitary experiment on the part of nature to produce a respiratory pigment having manganese as its metallic basis.³²

8. Cobalt and Nickel

These metals are only rarely found in tissues, and certainly do not possess the universal importance of copper and manganese. There is no satisfactory proof of the presence of cobalt in vertebrate tissues, but it is occasionally found in invertebrates, and, curiously enough, this is generally the case in species which also have a predilection for nickel. Nickel is a more widely distributed element than cobalt. In human beings it is said to be concentrated chiefly in the pancreas,³³ though this awaits confirmation. It is found in some plants, especially the tropical spices, to a considerable extent.³⁴ In invertebrates it has an irregular distribution in polychaetes and molluscs—usually in association with cobalt. A fact which illustrates the extraordinary selectivity exercised by some organisms for these metals is that, of two species, *Iiahotis* has a high nickel content (0.004 per cent.) without cobalt, while *Archidoris tuberculata* contains cobalt (0.003 per cent.) but no nickel.³⁵ Although nothing is known of any natural function of either of these metals, cobalt in mammals has the power of producing a true red-cell polycythaemia—a fact which may have therapeutic applications.

9. Aluminium

It may be accepted that aluminium is present as a constant constituent of plant and animal tissues, but this is not surprising in view of the wide distribution of this element in soils. On an average human diet the intake of aluminium is somewhere about 12 mg. per diem, of which about half at least comes from the food and not from cooking utensils.³⁶ We have no knowledge of whether it is an "essential" element for the tissues, or whether it is merely taken up passively. In any case, in the amounts absorbed from an ordinary diet it appears that it does no harm, and that there need be no fear of toxic effects from the use of aluminium cooking vessels.

10. Zinc

Zinc is found universally in tissues, and must be regarded as essential to life. It occurs in blood in an amount of from 1.5 mg. to 2.5 mg. per 100 c.cm., and is, in contrast to copper and manganese, mainly present in the cells.³⁷ It occurs in human milk, and in the milk of the cow and ewe, in amounts of 2 to 3 mg. per litre. In all these cases the amount is highest at birth, with a sharp drop to a steady level after ten to fifteen days.³⁸ In the tissues it occurs in greatest amount in the genital organs and in the thyroid, and in the case of the liver recent work suggests that there is a pre-natal store of zinc as well as of copper and iron³⁹—the birth value being of the order of 114.3 mg. per 100 grams (dry) as against 32.4 mg. per 100 grams (dry) in the adult. This, if confirmed, must be regarded as proof of the necessity of the metal for life. Recent work has shown that zinc appears to be essential for normal reproduction in the rat, though it does not appear to be essential for growth.⁴⁰

11. Silver

This element has a very curious distribution. In plants it occurs in some species, but the evidence does not suggest that it is universal. It has, however, a stimulating effect on the growth of watercress, and in the tobacco plant the addition of silver inhibits root growth but causes a precocious development of the nicotine-secreting hairs.³⁰ In fungi it sometimes occurs in remarkable amounts—up to 0.2 per cent. (dry)—and it is a curious fact that in every specimen of edible fungus so far examined Ramage has found silver. This applies not only to English specimens, but also to South African.³⁴ In human tissues Zbinden found it in blood and in all the organs he examined.⁴⁴ Using a less delicate method, Ramage and I have found it in every investigation in about 30 per cent. of the specimens. We are in agreement with Zbinden that the thyroid gland is especially rich in silver, and the same appears to be true of the tonsil.³⁰

12. Arsenic

There is a growing body of evidence that minute traces of arsenic are of widespread occurrence in tissues, and that the element is of physiological importance. In human blood it occurs in an average amount of 63.8 γ per 100 c.c.m.³¹ A very interesting feature is that during menstruation the figure rises by 50 per cent. to an average of 92.5 γ , and in pregnancy it rises to a maximum during the fifth and sixth months, reaching a figure of 220 γ . Similar values are apparently also found in carcinoma.

13. Cadmium

This metal, which is closely related chemically to zinc, was never described in living tissues until it was found spectroscopically in 1931 by Fox and Ramage.³¹ The extraordinary feature is that apparently it occurs in one species only, the common scallop (*Pecten maximus*), but in every specimen of that species, obtained from four different localities, cadmium was present in the tissues. This suggests that, as with vanadium, nature has made an experiment with cadmium which has not been carried further.

14. Lead

Lead occurs in the tissues to a much greater extent than is usually believed. Its ubiquity is shown by the fact that it was found in the human eye on spectroscopic examination.⁴⁵ Lead is a normal constituent of sea-water and has been recorded as present in crustacea and molluscs.³² There is nothing to indicate whether in the minute amounts constantly found it is of physiological importance or not.

15. Tin

In human beings minute amounts of tin have been described in the brain, spleen, and thyroid.⁴⁴ In oxen, horses, and sheep the tin content varied from 0.5 mg. per kilo (dry) in the stomach to 4 mg. per kilo in the pancreas.³³ The muscle of the tongue gave 12 to 16 mg. per kilo, while the mucous membrane of the tongue gave 18 to 26 mg. per kilo. These extraordinarily high figures for the tongue, and especially for its mucous membrane, suggest that this region of the body may have unsuspected functions.

16. Vanadium

Vanadium occurs regularly in the blood in certain ascidians, where it forms 5 to 10 per cent. of the respiratory pigment.⁴²

This list of elements found in tissues is not intended to be complete—thus, titanium has been described in human tissues and human milk,³⁷ uranium in the chicken's egg, molybdenum in apples, etc.—but is intended as a

justification of the thesis advanced at the beginning, that the normal metabolism of the body is based on a much wider chemical foundation than was originally thought to be the case. The determination of which elements are of functional importance and which are accidental in their presence must await further work, though it seems clear that copper, manganese, and zinc are of universal importance. The fact that gold is a constituent of sea-water, but is not found in marine organisms, suggests that the other rare elements owe their presence at any rate to a selective absorption. It is unlikely that the whole of life makes use of the same elements, since nature appears undoubtedly to have made experiments which have subsequently been abandoned—this is the best explanation of the species rigidity of the occurrence of vanadium and cadmium. It would not be adequate to leave the matter here, and a few further general remarks seem to be worth making, though it is clear that we are merely on the threshold of a branch of knowledge, the very existence of which is only a recent discovery. The following are points of view which appear to be matters of legitimate speculation.

INTERRELATIONSHIPS BETWEEN MINERALS

It is already clear that the mineral constituents of the body are not independent entities, and that in various ways their physiological activities are interrelated in the directions of either antagonism or synergism.

Antagonism.—The most obvious instance of a biological antagonism can be seen in the mutual relations of calcium and magnesium, for which there is abundant evidence that need not be detailed here.

Synergism.—This is a field which will undoubtedly play an important part in the dietetics of the future. The most striking instance is provided by the mutual relations of calcium, iron, and copper. It has been known for some time that in some way calcium conserves iron in metabolism. In our examination of infant livers³⁵ we obtained a remarkable degree of correlation between the two metals, which is indicated in the figure. The mean

(Reproduced by permission of the Royal Society.)

curve was obtained by plotting the average percentages of calcium found for each percentage of iron. It will be seen that the two tend to increase together. If lines are drawn parallel to this mean line at a distance representing a variation of ± 0.04 per cent., it is found that 81 per cent. of the cases fall within these limits. It was further found that the average birth value of iron (0.3 per cent.) was never obtained when the amount of calcium was below a certain limiting figure (0.08 per cent. dry).

Similar, but less marked, relations were found to exist between iron and copper, and consequently between calcium and copper. It was noteworthy that the limiting calcium figure for the average copper figure at birth was the same as for iron. There is clearly a close relation between these three metals which cannot be without significance for further nutritional studies. This mutual

relation has clinical significance, for it is stated by Davidson¹¹ that "a normal blood level can be maintained on a diet rich in calcium and moderate in iron, but that anaemia will occur on the same iron intake if the calcium is reduced." In plants the influence of boron on calcium assimilation and of silicon on phosphorus assimilation provide examples of similar close mutual relations. In a satisfactory diet a proper balance between the various mineral ingredients is probably a feature the importance of which comes next to that of the actual presence of the minerals concerned. It is hardly realized yet how much the balance of the "trace" elements may be altered in our diet by the widespread use of various chemical fertilizers and insecticides, but there can be little doubt that with advance in knowledge this will need investigation.

MINERAL DEFICIENCY

In view of the great advances which have followed the discovery that many human beings are living on a diet deficient in vitamins, it is natural to ask whether there is any evidence of a similar deficiency with regard to minerals. It is well known that in some districts there is a shortage of iodine, in which endemic goitre is attributed. In general, however, it may be said that the clearest evidence of deficiency is found in the case of iron, the effects of which are probably accentuated by a parallel shortage of calcium. This is especially the case with the women and the children of the working classes. The famous investigation of Helen Mackay showed that a large number of London children were deficient in iron,¹² and the same was found for the working women of Aberdeen by Davidson.¹³ In this district there are no similar observations, but we have found that meconium, while rich in other metals, has practically no iron,¹⁴ indicating that at any rate the average mother here is unable to provide the foetus with an excess of iron. It might be assumed that this is due to the total absorption of iron by the foetus for storage in the liver; but copper, which is also stored, appears in the meconium in considerable amounts. There is no doubt that the usual diet of the poorer classes in this country is deficient in iron, and that the burden of this falls mainly on women and infants. It must be remembered that calculation of the iron intake based on analysis of uncooked material is very unsatisfactory. In the case of broccoli, for example, 50 per cent. of the iron is lost by boiling for twenty minutes¹⁵—a particularly important fact since vegetables form one of the chief sources of iron in the food.

The case with regard to copper and manganese is not so clear. There are several lines of evidence which suggest that it is rare for there to be a deficiency of these metals in human beings. The average intake of copper in Aberdeen was found to be about 3 mg. per day,¹⁶ which is certainly enough to meet all requirements. This is probably the explanation of the fact that there has never been any satisfactory evidence of the medicinal use of copper having the same effect in nutritional anaemia as it undoubtedly has in experimental animals, in spite of occasional individual successes. The fact that meconium from this district was found to contain strong copper lines on spectrographic examination indicates that the mother is usually able to supply the foetus with all the copper it needs. Although there is nothing to suggest any common deficiency of copper in human diets, this does not occur with animals. In Florida a nutritional anaemia of cattle has been shown to be due to a deficiency of copper in the vegetation.¹⁷ The amounts of the other metals, such as manganese and zinc, which are necessary and essential that there does not appear to be either any evidence of any widespread deficiency.

ISOTOPES

The extraordinary selectivity displayed by living organisms with regard to the elements employed in their make-up leads one to ask whether this same selectivity extends to the isotopes of the elements. For some time I had wondered whether the explanation of the colossal doses of iron now employed in the treatment of anaemia and of some spinal cord degenerations might not find their explanation in the fact that possibly only one of the two isotopes of iron could be employed in the synthesis of haemoglobin or had a therapeutic effect on the nervous system. A selectivity on the part of life, not only as regards the elements but also as regards their isotopes, is so highly speculative¹⁸ that but for the fact that it now has some experimental basis I would not mention it.

Hydrogen consists of two isotopes, of mass respectively (omitting decimals) 1 and 2, which are usually written as H^1 and H^2 .¹⁹ These are present in ordinary hydrogen in a relative abundance ratio of roughly $H^1:H^2$ as 6,500:1, though the exact figures are not settled. Recent physical research has succeeded in effecting an almost complete separation between these isotopes, and it has thus been possible to make "heavy" water, in which all the hydrogen consists of the heavy H^2 isotope—although the amount that can be made is, of course, very small. Such water differs from ordinary water in several physical properties. It has a higher freezing point ($3.8^\circ C.$) and boiling point ($101.42^\circ C.$), but the startling fact is that such "heavy" water is incapable of supporting life. Tobacco seeds failed to grow in it, while controls in ordinary water grew normally. In water in which half the hydrogen consisted of the heavier isotope, development took place, but only at about half the speed of controls in ordinary water. Thus of the two kinds of atom of which ordinary hydrogen is composed, one appears to be inimical to life. Seeing that oxygen and carbon have also at least two isotopes each, the complexity of the organic chemistry of the future stuns the imagination. The future applications of this method of research to the mineral constituents of the body may yield very surprising results.

Studies on the mineral basis of life are only in their very early infancy. They are of extreme interest in that the evidence so far collected tends to show that many of the elements resemble the vitamins in being necessary only in minute amounts. It is clear that, as Bertrand has said, the body cannot be regarded as a democracy, but rather as an oligarchy, in which a large amount of passive elements are ordered and governed by minute amounts of active ones, and the biological investigation of these very active elements cannot but be fruitful.

CARCINOMA OF THE MAXILLA AND ETHMOID

A SURVEY OF THE NOTES OF FIFTY CASES

BY

EDWARD D. D. DAVIS, F.R.C.S.

SURGEON, NOSE, THROAT, AND EAR DEPARTMENT, CHALKING CROSS HOSPITAL

Carcinoma of the maxilla is fortunately comparatively rare, and statistics show that it accounts for about 1 to 2 per cent. of all malignant tumours.¹ This paper is limited to a survey of fifty cases of carcinoma of the maxilla and the ethmoid seen during the past twelve years. All other tumours of the maxilla have been excluded. These cases can be divided into two definite groups.

TWO GROUPS OF CASES

The first, or lower, group consists of nine cases of squamous epithelioma arising in the alveolus or hard palate in the region of the molar teeth. The growth extends into the cheek sulcus, or may begin there, and quickly involves the cheek. Sooner or later it bursts through into the antrum and, taking the line of least resistance, fills the antrum with a soft, vascular, necrotic tumour. This squamous epithelioma may commence as the usual typical ulcer, or the growth may be deep-seated and of the burrowing kind, and when it appears on the surface it has already infiltrated the cheek and

antrum. The section of this deep-seated tumour was called an adenocarcinoma.

The second, or upper, group comprises forty-one cases in which the growth arose in the upper part of the nose. At the time of operation it is so extensive and necrotic that it is almost impossible to say where it originally started. There was definite evidence in fifteen of these cases to show that it originated in the floor of the orbit around the infra-orbital canal. In ten patients it began in the ethmoid and spread to the floor of the orbit. In the remaining sixteen the origin of the growth was doubtful. However, in all these it filled the antrum, being attached to the orbital periosteum and having spread into the ethmoid, even to the anterior fossa of the skull and to the other nasal sinuses.

The sections have been described as those of squamous carcinoma, adenocarcinoma, columnar-celled carcinoma, pleomorphic carcinoma. One or two were first called sarcoma, and then changed to squamous carcinoma. There were two endotheliomata arising from the middle turbinal. The sections sometimes revealed variation in the same tumour. The adenocarcinomata were those which arose near the infra-orbital canal. Though pathologists agree that these growths are undoubtedly carcinomata, there is considerable diversity in the nomenclature adopted for the type. Pathologists vary as to the Christian name, so to speak, which they give to a particular carcinoma. As would be expected, French pathologists have a different nomenclature from the British, and between most countries this variation exists. However, to the surgeon and to the clinician the pathology was the same—a rapidly growing malignant epithelial tumour, more malignant than the lower group commencing in the alveolus. The two endotheliomata were definitely less malignant than the true carcinomata. It may be possible to apply Broders's classification of malignancy to these carcinomata. It would be of greater importance to know which types are more radio-sensitive than others.

The first, or lower, group were more commonly seen at a dental hospital or in a general surgical clinic. The second, or upper, group came to the nose and throat clinic or were sent to that clinic from an ophthalmic hospital, so that the difference in the numbers of the two groups is relatively of no importance. There were twenty-seven males and twenty-three females; the ages were from 45 to 70. The younger the patient the more malignant the growth. The patients' surroundings and occupations showed a very wide variation, and the cause of the tumour was as unknown as that of cancer. There was no history of previous disease, and no suppuration of the nose, and there was nothing which could be called precancerous.

SIGNS AND SYMPTOMS

Early diagnosis is of the utmost importance. This should not be difficult in the first, or lower, group of cases; but in spite of this nearly all these came too late for successful extirpation. There was the typical epitheliomatous ulcer, or the deformity of the alveolus and palate with painful or loose teeth. It was rarely necessary to remove a piece for section before operation. If a piece is removed the wound should be sealed by the diathermy button to prevent sepsis or a flare. The early diagnosis of the upper, or second, group of cases is well-nigh impossible, because cancer in itself does not produce any specific symptoms or signs, and it is only when the cancer cells form a tumour that a series of mechanical results appear. Furthermore, the development of these is slow and insidious, particularly in a hidden cavity like the nose, and a patient often only consults a doctor when such symptoms are well marked—frequently too late for successful removal. The general signs, such as blood changes, were of no practical value in the diagnosis.

The most frequent first symptom is a persistent pain in the cheek, radiating to the forehead or temporal region, and accompanied by a blood-stained discharge from one nostril in a patient of cancer age. X-ray photographs should be taken when there is unexplained pain in the distribution of the infra-orbital nerve, and may perhaps lead to an earlier diagnosis. Chronic sinus suppuration accompanied by severe pain, which persists after the sinuses have been drained by operation, demands a search for a tumour. The teeth are frequently blamed for the pain and are extracted. Severe epistaxis in an elderly patient, not arising from the usual causes, with pain in the cheek, should raise suspicion of a growth. In this series of cases the average duration of such symptoms before the patient was seen was three months. An examination of such a case revealed a vascular, polypoid-looking swelling in the middle of the meatus of the nose, which bled freely when probed. Transillumination showed a dark antrum, and an x-ray photograph demonstrated a still more marked opacity of that region. The improved x-ray technique now adopted for the nasal sinuses produces photographs which give such valuable information as to the extent of the growth that it is essential that these photographs should be carefully studied before operation. If there is any doubt as to the presence of a tumour after such signs, exploration of the antrum through the canine fossa, with preparations for a more extensive operation, is advisable. Later symptoms were proptosis, lachrymal obstruction, and expansion of the walls of the antrum, and finally (too late) a puffy swelling of the cheek below the infra-orbital margin, where the neoplasm had burst through the wall of the antrum. Secondary growths did not occur except in two or three of the advanced and inoperable cases, when the upper deep cervical glands near the base of the skull were involved.

RESULTS OF OPERATION

All the nine patients in the first, or lower, group were submitted to operation. One case was found to be inoperable, and a complete destruction of the tumour with diathermy or electro-surgery was impossible. There was recurrence of the neoplasm within twelve months. It was considered that a complete destruction of the growth by diathermy had been obtained in the remaining eight cases, but a recurrence appeared in five at the end of twelve months, and in three at the end of two years. Radium was implanted in three instances, with no beneficial result. The growth was well established in all these cases when first seen, but better results should have been obtained by operation and electro-surgery.

Of the forty-one cases of the upper, or second, group seven were obviously inoperable when first seen; the cheek was infiltrated and the orbit extensively invaded. These seven patients died in an average of three months after their first visit and six months from the apparent onset of symptoms. Radium was implanted in two of these with no beneficial result; in fact, one patient died of meningitis six days after the implantation of 20 mg. of radium, but the post-mortem showed that the tumour had burst through the roof of the ethmoid into the skull. Six patients only, out of the thirty-four, were free from recurrence for more than two years. Two of these had encephalomata and survived four and a half and five years respectively. Ohngren's results are decidedly better. Thirty-eight cases of carcinoma out of 101 were free from recurrence after two years.

OPERATIVE PROCEDURE

The operation I carried out have had the following characteristics: (1) a thorough exposure of the growth; (2) its removal as far as possible; and

(2) complete excision, followed by diathermy: the orthodox anatomical operation of excision of the upper jaw was discarded. The teeth are put in order as soon as possible after the patient is first seen, and as half of the hard palate is to be removed a denture or obturator of soft velum rubber is made and inserted immediately after the completion of the operation. The most satisfactory form of anaesthesia is the intratracheal, and was employed without any disadvantage. The external carotid artery was ligatured in two instances only, because it was considered that ligature did not diminish the haemorrhage. On the other hand, Ohngren has proved to his satisfaction that secondary haemorrhage after diathermy was materially diminished by ligature of the external carotid. He also advises that the ligature should be applied above the superior thyroid artery, because the clot has been known to be detached and carried into the internal carotid. Ligature is of more value when diathermy is applied to the fauces and soft palate.

The first, or lower, group of cases were attacked by dividing the upper lip in the mid-line and carrying the incision into the nostril, the cheek then being reflected upwards so as thoroughly to expose the alveolus. The neoplasm is excised with a free margin of healthy tissue with the diathermy knife. The floor of the antrum and a large area of the hard palate are removed, the cheek is carefully examined, and any growth is widely removed by diathermy.

In the second, or upper, group of cases permission should be obtained to enucleate the eyeball if a more thorough clearance of the orbit is likely to be required, but the orbital periosteum protects the contents of the orbit. The modified Ferguson incision is made from the fronto-nasal suture down the side of the nose, around the nostril, and through the upper lip. This incision can be made with the diathermy needle, which has the advantage of diminishing the haemorrhage. The cheek is reflected upwards and outwards to the malar bone, the infra-orbital margin is defined, and the whole bony wall of the side of the nose and antrum is removed. The tumour, with the floor of the orbit, is peeled off the orbital periosteum. The ethmoid infiltrated by the growth is coagulated by the diathermy button, and removed up to the base of the skull and as far back as the sphenoid.

Diathermy arrests the haemorrhage, and is applied whenever practicable and to any areas where growth is suspected. The hard palate and floor of the nose is not infiltrated by the tumour, but they should be removed to form a window, so that its area can be inspected and diathermy and radium applied after the skin incision has been closed. The details of the technique of the operation have evolved and have been improved in the later cases, when more experience had been gained. All the patients made an uneventful recovery, and not one died from the immediate or remote effects of the operation. Meningitis and injury to the eyeball was expected, but particular care was taken in dealing with the tumour in these areas. The contents of the orbit can be protected by a thin spatula insulated by a covering of rubber or vulcanite. Ohngren, who has operated on a large number of these cases with diathermy, has seen meningitis, cerebral oedema, and cerebral abscess occur with and without radium application. The application of diathermy to the orbital periosteum, and also radium exposure, has been followed by necrosis of the eyeball. In three of the above cases blindness from optic atrophy appeared with the recurrence of the growth. After diathermy, patients frequently complain of the offensive odour, in spite of irrigation with encol. Ohngren has painted the charred area with a 2 per cent. permanganate solution and irrigated it with a 1 in 2,000 permanganate solution with success.

The results of radium therapy up to the present has been disappointing. Deep x-ray exposure and telerradium—that is, exposure to the radium bomb—has been tried before operation, but the lowered state of nutrition, the risk of the increased sepsis, and the fact that the inflammatory reaction after radiotherapy delays operation counteract any possible beneficial result of such exposures. Treatment with radium immediately after operation delays healing, and the severe sepsis which follows makes the patient desperately ill. The implantation of radium is unsatisfactory, and has increased the pain and discomfort. The surface application of radium—that is, radium in small doses fixed to the upper surface of the dental obturator and applied for a prolonged period some weeks after diathermy—may produce better results. The combination of electro-surgery and x-ray and radiotherapy is now advocated. A free access to the growth is of course essential.

It is generally found at the operation that the tumour is more extensive than anticipated; on the other hand, cases, which appear to be hopeless often do better than expected. The difficulty of early diagnosis and the inaccessibility of ethmoidal carcinoma make it doubtful whether such a mutilating operation is worth while. Nevertheless, the number of successful cases seen in Professor Holmgren's Clinic at Stockholm is encouraging. Operation relieves the patient of pain, and he has the satisfaction of knowing that determined effort has been made to rid him of the disease with a hope of success. The condition of the inoperable patient is truly a miserable one.

THE LABORATORY DIAGNOSIS OF ENTERIC INFECTION

WITH REMARKS ON THE PERSISTENCE OF INFECTION

BY

A. W. DOWNIE, M.D.

LECTURER IN BACTERIOLOGY, UNIVERSITY OF MANCHESTER

AND

R. W. FAIRBROTHER, M.D., M.R.C.P.

LECTURER IN BACTERIOLOGY AND ASSISTANT DIRECTOR OF THE PUBLIC HEALTH LABORATORY, UNIVERSITY OF MANCHESTER

Although the incidence of enteric infection in this country has greatly diminished during the present century, the continued occurrence of small outbreaks of sporadic cases indicates the endemic nature of this disease. The reason for such persistence of infection is largely the presence of carriers or undiagnosed cases in the community, as demonstrated in an unfortunate manner by the recent outbreak at Malton (Shaw, 1933). A recently published study of enteric carriers in Glasgow (Browning *et al.*, 1933) gives details of individuals who were excreting bacteria of the enteric group over a period of years. As the ultimate source of infection must always be the discharges of human beings harbouring the particular organisms it is certain that unrecognized carriers are responsible for many of the sporadic cases of the disease.

It is thus obvious that control of enteric infection in a community depends largely on early diagnosis of cases, examination of contacts, and repeated examination of convalescents until they can be pronounced free from infection. The following report illustrates the necessity for this measure, and deals with the laboratory examination of specimens from cases in the north-west of England. Only cases which have been proved by the isolation of

the infecting organisms have been considered. Cases in which diagnosis was by agglutination tests have been omitted.

MATERIAL REVIEWED

During the last three years the following organisms have been isolated from individual cases under examination:

<i>B. typhosum</i>	25 cases
<i>B. paratyphosum</i> A	1 case
<i>B. paratyphosum</i> B	48 cases
<i>B. enteritidis</i>	6 cases
<i>B. aertrycke</i>	13 cases

The last two organisms were associated with food poisoning, except in two cases of prolonged fever from which *B. enteritidis* was isolated by blood culture. These bacteria are not considered further in this paper. The typhoid and paratyphoid infections occurred in twenty-seven municipalities; their sporadic distribution indicates the endemic nature of the diseases.

Cultures were isolated from the blood, faeces, or urine, but only certain of the results of the faeces and urine are considered in detail. These serve to illustrate the persistence of infection after the febrile period.

BLOOD EXAMINATION

1. *Culture*.—In all cases where blood was received for serological examination the serum for agglutination tests was removed from the clot, which was then placed in a tube containing 10 c.cm. of MacConkey's double strength bile-salt-lactose-peptone-water medium. After twenty-four and forty-eight hours' incubation at 37° C. subcultures were made from this medium on plates of MacConkey's agar or tubes of Russell's double sugar medium. By this technique the infecting organism was frequently recovered in pure culture. Table I shows the number of positive results obtained, and the stage of the disease at which the examination was made.

TABLE I

Organism	No. of Cases Examined	No. Positive	Day of Illness
<i>B. typhosum</i> ...	20	11	7th-8th
<i>B. paratyphosum</i> B ...	21	6	5th-11th

The proportion of positive blood cultures corresponds very closely to that obtained by Smith (1932), using a similar technique.

2. *Agglutination Tests*.—In the early stage of enteric infection examination of the faeces and urine frequently gives negative results. More useful information can usually be obtained at this time by the examination of the blood, first, by cultural examination for the presence of the infecting organism, and, secondly, for the presence of agglutinins in the serum. Cultural examination of the blood has already been mentioned, and in the typhoid cases, as shown in Table I, it proved particularly useful. Specimens of blood were not received from all the proved cases in this series, but in those examined the agglutination test gave definite evidence of infection. Since the method of qualitative receptor analysis was introduced by Weil and Felix (1920), the value of the method has received ample confirmation. Our routine procedure has been to combine the qualitative and the quantitative methods by testing dilutions of the serum from 1 in 20 to 1 in 2,560 with both "H" and "O" suspensions of various organisms of the enteric group. The suspensions used were obtained from the Standards Laboratory, Oxford. In Tables II and III, however, only the results with the suspensions of *B. typhosum* and *B. paratyphosum* B have been given. In all cases the infecting organism was isolated from the blood, faeces, or urine.

In Table II the agglutination reactions obtained in cases of *B. typhosum* infection are given.

TABLE II—Typhoid Fever: Agglutination Tests

Case	Sex and Age	Day of Illness	Titre			
			T "H"	T "O"	B "H"	B "O"
1	M 9	9	83	0	0	320
2	F 5	11	640	1,280	0	0
3*	M 47	12	40	0	0	0
4*	F 43	9	320	160	0	160
5	M 60	10	0	0	0	0
		35	0	80	0	0
6*	M 17	15	2,560	180	0	80
7	F 8	7 2	0	320	0	0
8	F 53	11	40	320	0	160
9	M 10	12	1,280	1,280	0	160
10	M 60	8	0	80	0	0
11	M 21	10	640	640	0	0
12	F 56	—	2,560	0	0	0
13*	F	14	40	80	0	160
14*	M 18	12	640	320	0	0
15*	M 70	7	160	320	0	0
16*	M 60	8	320	320	0	160
17*	M	8	320	0	0	0
18*	F	10	80	640	0	0
19*	F 15	—	160	320	0	0
20*	M 53	8	2,560	640	0	0

* *B. typhosum* recovered by culture of blood clot.

T "H" and T "O" = suspensions of *B. typhosum*.

B "H" and B "O" = suspensions of *B. paratyphosum*.

— = not known.

0 = negative in 1 in 40 dilution.

It is seen from the above table that the "O" titre was in several instances higher than the titre of "H" agglutinins, and in three cases "O" agglutinins were present in the absence of the latter. In one case (Case 5) the agglutination reaction for both suspensions was negative ten days after the onset, and positive only for "O" on the thirty-fifth day of illness. Cross-agglutination with "O" suspensions of *B. paratyphosum* B occurred in seven of the twenty cases, but cross-reactions with the corresponding "H" antigen were never observed. These results support the findings of others, that, in certain cases, "O" agglutinins only are produced in response to infection, and also that these may appear earlier in the disease than the "H" agglutinins (Smith, 1932; Wyler, 1932).

The results in infection with *B. paratyphosum* B were somewhat different, as will be seen from a study of Table III.

Here "H" agglutinins for *B. paratyphosum* B were constantly present, the titre was generally much higher than in the typhoid cases. Agglutination of the "O" suspension of *B. paratyphosum* B occurred with all sera, except two, but the titre was never greater than that given by the "H" suspension. Cross-agglutination with the "O" suspensions of *B. typhosum* occurred in a similar proportion of sera as shown for *B. paratyphosum* B in Table II. These serological findings are similar to those recently recorded by Smith (1932), Grier and Scarborough (1932), and others. Numerous other serological tests on cases, which were diagnosed as typhoid or paratyphoid fever, but from which the organism was not isolated in our laboratory, have not been carried out. These gave findings similar to those recorded in Tables II and III.

The results seem to justify the conclusion that in the majority of cases evidence of infection may be obtained after the first week of the disease, or even earlier, by means of the agglutination test.

In the course of our work the sera of individuals who had received prophylactic T.A.B. vaccine—mostly between 1914 and 1918—have frequently been examined, but these rarely gave rise to any difficulty. In the absence of infection in such persons agglutinins, if present, were usually of a low titre (1 in 640 or less), and reacted with the "H" suspensions of both *B. typhosum* and *B. paratyphosum* B, and frequently also with *B. paratyphosum* A, while agglutinins for the "O" antigens were almost invariably absent.

FAECES AND URINE EXAMINATION

Culture was made from the faeces directly on MacConkey's agar medium, and also by the brilliant-green technique using 1 in 150,000 and 1 in 300,000 concentrations of the dye. In the typhoid cases no advantage was observed by the brilliant-green method, which always gave negative results when direct culture was negative, and even in a few instances when the direct method was positive. In all the paratyphoid cases, when the organism was recovered by direct culture it was also isolated by the brilliant-green method; but in seven cases where direct culture failed brilliant-green enrichment gave positive results. Culture of the urine was made directly on plates of MacConkey's agar, and again after incubation of the urine for twenty-four hours in the presence of brilliant green added to make a final concentration of approximately 1 in 250,000. All cases positive by the brilliant-green technique were also positive by direct culture.

* *B. paratyphosum* B recovered from blood clot.

The results of culture from faeces and urine in relation to the duration of the illness in the typhoid cases are

shown in Table IV. In Table V similar results are shown for those cases of paratyphoid fever where more than one examination was carried out. Of the total number of cases mentioned above, single examinations only were carried out by our laboratory in certain instances; these have been omitted here owing to insufficient data.

inations were made showed positive cultures at the time of the last examination—for example, Cases 1, 16, and 20, Table V; of these Cases 1 and 20 are still under observation. Of the sixteen typhoid cases shown in the table the organism was recovered from the faeces, in one case six months, and in another eighteen months, after the onset of illness, and in two cases from the urine after four months and twelve months. Of the twenty paratyphoid cases shown in Table V, six were still excreting paratyphoid bacilli after two months; of these one had the organism in both the urine and the faeces after twenty months.

The results indicate that in the examination of convalescents it is necessary to emphasize the fact that a single negative examination of the faeces and urine is not sufficient to justify the conclusion that an individual is free from infection. Cases 19 and 27, Table V, illustrate this point. Here the excretion was intermittent; Case 19 gave positive cultures thirteen and twenty days after previous negative examinations. The results do not indicate that either age or sex plays an important part in determining the persistence of infection with either typhoid or paratyphoid bacilli.

DISCUSSION AND CONCLUSIONS

The fact that the control of enteric infection depends to a large extent on the early diagnosis of cases and the detection and control of carriers was mentioned above. In the diagnosis by laboratory examination the guiding principles, although perhaps not sufficiently appreciated, are well established, and are illustrated by the findings recorded above.

Towards the end of the first week—and the patient is frequently ill a few days before enteric infection is suspected—examination of the blood by cultural methods and agglutination tests with the serum will in the majority of cases afford evidence of the nature of the disease. The evidence obtained by the agglutination test should, however, be confirmed by isolation of the infecting organism from the faeces or urine wherever possible. Later in the course of the illness agglutination tests with the patient's serum generally give more marked reactions and, while blood cultures are less frequently positive, the isolation of the causal organism from the urine and faeces is more readily effected, especially during the second and third weeks.

In the detection of carriers examination during convalescence is of the utmost importance. The carrier state may be merely temporary, the organisms being excreted for some weeks or months after the febrile period. Such cases tend to clear up spontaneously, but in order to prevent the spread of infection from these, adequate methods of testing for freedom from infection during convalescence must be employed. At least three successive negative reports on faeces and urine should be received at weekly or fortnightly intervals before a person can be considered probably free from infection. In the permanent carrier excretion of the organisms in faeces or urine, sometimes intermittent, persists indefinitely, and this presents a much more difficult problem: The only satisfactory method for removing the source of infection appears to be operation (Browning *et al.*, 1932).

The necessity for the examination of contacts is illustrated by Cases 1 and 20 in Table V. These had no clinical manifestations of infection, and were detected in the examination of members of the families where several cases of illness had occurred. The investigations on these two cases showed that they were carriers of the permanent class, and it would appear that they were probably the original source of the associated outbreaks.

Although there is nothing new in this communication the experiences of this laboratory may serve to emphasize

The examinations in Tables IV and V were incomplete in the sense that, although the majority of the cases apparently made a complete clinical recovery, the probability of freedom from infection was not established in all. Certain of the cases from which repeated exam-

to physicians and laboratory workers alike the necessity for bacteriological control of enteric fever.

COLLAPSE THERAPY IN BRONCHIECTASIS

A WARNING

BY

H. P. NELSON, M.D., F.R.C.S.

ASSISTANT SURGEON TO THE LONDON HOSPITAL FOR DISEASES OF THE CHEST

Collapse therapy has earned a great reputation in the treatment of pulmonary tuberculosis. A bronchiectatic cavity, on the other hand, differs from a tuberculous one in that it is lined with epithelium, and, however long two epithelial surfaces are in contact, they will never unite. In bronchiectasis, therefore, the procedure cannot be regarded as a curative, but only as a palliative treatment. Collapse therapy in bronchiectasis possesses, however, a disadvantage which I do not think is fully appreciated by those who advocate it—namely, that it greatly diminishes the possibility of a successful lobectomy, should this become necessary. In the modern one-stage lobectomy it is essential to obtain an early expansion of the remaining lobe, and so obliterate the pleural space before infection can set in. A paralysed diaphragm removes the principal factor in expanding the lung, and a prolonged artificial pneumothorax so anchors the remaining lobe that it will not expand quickly enough. I would like to quote two unfortunate experiences which have prompted me to give this warning to others.

Case 1.—A woman, aged 28, was admitted to St. Andrew's Hospital, Bow, on January 11th, 1933. Seven years ago she had a so-called pneumonia on the right side, followed by an empyema which healed with rib resection and drainage. Since that time she had had a persistent cough, with about one ounce of offensive sputum every morning. Four years ago she started to spit up blood (about four ounces at a time), and this recurred three or four times every year. By 1932 the condition had become much worse, and the bleeding was more frequent. Her sputum was negative for tubercle bacilli. Lipiodol demonstrated severe bronchiectasis in the lower lobe. In November, 1932, a right phrenic evulsion was performed, but following this there was no improvement in the symptoms. In January, 1933, I saw her for the first time. She was then having severe haemoptyses every week, was anæmic, and it was obvious that something had to be done to try to relieve her condition. On February 8th I performed a right basal lobectomy. Owing to the previous empyema there was a mass of adhesions round the lower lobe, particularly on its costal surface, but by entering the empyemic space I managed to strip the lobe free. There were adhesions in the interlobar fissure, but none over the upper lobe. The day following the operation the patient was anæmic, and there was a small shift of the mediastinum. During removal of the lower lobe a small portion of it slipped into the pleural cavity. At the end of the operation the chest was drained by a closed waterlocked drainage. The patient lay in the prone position for the first 24 hours, and then on the right side after operation. A very good expansion of the right pleural cavity was obtained, and the patient was discharged on the 14th.

On March 1st the patient was examined and the whole remaining lung was found to be expanded. The patient was discharged on the 14th, and on the 21st she was re-examined. The patient was found to be well, and the remaining lung was found to be expanded.

and there is extreme risk of the patient dying from an infection of the pleural cavity.

Case 2.—A girl, aged 19, was admitted to St. Bartholomew's Hospital on September 21st, 1933, under Dr. F. G. Chandler. At the age of 3 she had had double pneumonia, and since then had had cough and sputum. In 1929 lipiodol demonstrated a bronchiectasis in the left lower lobe. She then had several ounces of offensive sputum daily. An artificial pneumothorax was therefore induced, and maintained with monthly refills of 500 c.cm. There was at no time any pleural effusion. The pneumothorax succeeded in reducing her sputum to a few drachms of inoffensive sputum daily, but by 1932 this had started to increase again. The lung was almost completely collapsed, except for a small part situated behind the heart shadow. Lipiodol demonstrated dilated bronchi in the collapsed portion of the lung. By September, 1933, she was producing one ounce of sputum in the twenty-four hours. A lobectomy was therefore advised, and was performed on October 17th. On opening the chest I found that the whole pleural cavity was lined by a thick white membrane, which completely obscured the anatomical landmarks. This was stripped off the lower lobe and a left lower lobe lobectomy performed, but with some difficulty owing to adhesions in the interlobar fissure. After removing the lobe I attempted to debride the white membrane off the upper lobe. This, however, was only partially successful, as it was firmly adherent in one place. At the end of the operation the chest was drained with a closed waterlocked drainage. This patient now (December, 1933) has a complete empyema on the left side, and there is practically no expansion in the remaining upper lobe. I fear that we will therefore have substituted a large chronic empyema for a left basal bronchiectasis.

In an artificial pneumothorax of more than a year's duration, even in those cases where there is no pleural effusion, the lung is likely to be encased in a white membrane and expansion of the remaining lobe therefore severely hampered. In future, before performing a lobectomy in a case of artificial pneumothorax, I shall inspect the pleural cavity with a thoracoscope.

DISCUSSION

After a phrenic evulsion for a basal bronchiectasis there may be a temporary improvement, but subsequently, when the diaphragm has completely atrophied, the patients return to the same, or a worse, condition. In cases of dry bronchiectasis, suffering from haemoptysis only, I have seen a definite improvement in symptoms following paralysis of the diaphragm. It is, however, advisable first to try a temporary paralysis, by crushing the nerve, to see if this is going to be effective in controlling the bleeding.

Artificial pneumothorax frequently fails owing to extensive pleural adhesions, but when a complete collapse is obtained the symptoms may disappear, as in those cases quoted by Dr. F. G. Chandler and referred to by Dr. Beaumont in the correspondence in the *British Medical Journal* of October, 1933. The collapse must, however, be maintained by refills for the rest of the patient's life, and, should obliterative pleurisy develop, with subsequent expansion of the lower lobe, one has probably burnt one's boats as far as lobectomy is concerned.

Thoracoplasty for basal bronchiectasis has, on the whole, given extremely bad results, and involves the sacrifice of a whole lung for a basal lesion, which is obviously wrong. But this operation still has a place in the treatment of unilateral bronchiectasis, when all the lobes are grossly affected and there is a large quantity of sputum. By means of a very extensive resection it is possible in these cases to reduce the sputum from, say, 20 ounces to one or two ounces; occasionally, they may even be sputum free, but in the majority it recurs again—although never, of course, to the same extent as before operation.

Thus the choice of therapy in basal bronchiectasis seems to me to rest between (a) posture and bronchoscopy, and

(b) lobectomy, which in selected cases carries a mortality of between 8 and 10 per cent.

CONCLUSION

The object of this paper is to point out that, when collapse therapy is applied to cases of bronchiectasis, it must be appreciated that such therapy may exclude the possibility of a subsequent lobectomy, should it become necessary.

Memoranda

MEDICAL, SURGICAL, OBSTETRICAL

HERNIA OF THE LUNG

This condition, although rare, is nevertheless of sufficient clinical interest to justify recording the details of a case which came under my notice. Most surgical textbooks give little more than a passing reference to the subject.

CASE HISTORY

A miner, aged 30, was injured while at work in the pit on January 28th, 1929, being struck heavily on the back by a loaded "tub." He was admitted to the General Infirmary at Leeds under the care of Mr. J. F. Dobson soon after the accident. He was found to have a fracture of the body of the right scapula, fractures of the second, third, and fourth right ribs in the antero-lateral wall of the thorax, and a considerable subcutaneous tearing of the fibres of the overlying pectoralis major. He was treated by the application of strapping, and was discharged to the care of his panel doctor ten days later. Soon after his arrival home he had what was described as an attack of acute bronchitis.

He was next seen in May, 1930, in the out-patient department, complaining of persistent pains and grating sensations over the right side of the chest, together with a spasmodic, unproductive cough. On examination there were harsh rhonchi and pleural friction sounds at the right base. X-ray examination of the chest showed malunited fractures of the second, third, and fourth ribs on the right side; the lungs were clear save for some increase in the root-shadows. In July, 1930, he was noticed to have a definite defect in the right chest wall and pectoralis major just above and to the outer side of the right nipple; the defect measured about three and a half inches in its vertical diameter and two and a half inches transversely. Through this defect a soft, crepitant mass appeared on deep inspiration, and, to a greater degree, on coughing; this was obviously a hernia of the lung. A corset with a pad to fit the defect was supplied.

Early in 1931 the man was given light work in the lamp-room at the colliery; he carried on this work satisfactorily for about two or three months, but subsequently he said he was unable to do any kind of work. In November, 1932, he was seen again, the corset controlled the hernia satisfactorily, but he complained of much spasmodic cough and shortness of breath. The hernia was no larger than when it was first seen, and there was no other abnormality to be detected in the chest on physical examination. X-ray examination of the chest showed nothing abnormal save the malunited fractures of the ribs.

COMMENTARY

Ætiology.—Hernia of the lung, or pneumatocele, may be of congenital or acquired type. The congenital herniae occur at the site of developmental defects in the thoracic parietes, and usually are incompatible with life. The acquired herniae may be of traumatic origin, or may follow some pathological process in the chest wall, or may even arise spontaneously. Most commonly they are of traumatic origin, following such injuries as stab and gunshot wounds which damage intercostal muscles or nerves, or the ribs themselves; some follow non-union or malunion of fractured ribs. The traumatic type of hernia

may appear soon after injury, or, in what Morel-Lavallée¹ termed the "consecutive" type, the hernia appears some considerable time after the injury, presumably on account of the yielding of scar tissue. Spontaneous hernia of the lungs occurs in such people as glass-blowers and wind-instrument players; it has also been recorded as occurring during labour. While traumatic cases may arise at any situation in the chest wall, spontaneous herniae usually are found anteriorly near the sternum, where the external intercostal muscle is replaced by membrane. At the corresponding place posteriorly the weak area is guarded by the mass of erector spinae, although Wightman² recorded a case of spontaneous pneumatocele in a trombone player beneath the trapezius and erector spinae, about one and a half inches to the right of the seventh dorsal spine. Sometimes the hernia protrudes into the neck through a defect in Sibson's fascia, and rarely into the abdomen through a defect in the diaphragm. Pathological causes include caries of the ribs, empyema necessitatis, lung abscesses, and the extensive operations of Estlander and Schede, but such herniae are very uncommon. Most pulmonary herniae occur in males, usually under the age of 45.

Prognosis.—Inflammatory changes may lead to the formation of adhesions between the sac and its contents, with resulting irreducibility; strangulation is rare, and spontaneous cure practically never occurs.

Treatment.—This must depend on the type of hernia and the cause. A hernia through a gap in Sibson's fascia is probably best treated conservatively; Chorel³ treated one such hernia by means of a pad and bandage. In cases of hernia through the bony chest wall treatment of the cause, such as caries of a rib, may result in cure. In traumatic and spontaneous cases palliative treatment may suffice; this involves the fitting of a corset with an obturator to fit the defect in the chest wall. It may also be necessary in such cases to modify the patient's occupation, although the disability when following occupational injuries sometimes diminishes in a remarkable fashion when the claim for compensation has been settled. Operative treatment should be directed in the first place to the treatment of any pathological process in the chest wall. Cure has been reported in cases of cervical pneumatocele after packing the hernial sac with iodoform gauze. Simple excision after ligation of the sac has been performed on several occasions. Montgomery and Lutz⁴ turned an osteochondral flap upwards from the fifth rib on a periosteal hinge to close a gap in the fourth intercostal space in a case of pneumatocele following a stab wound; this operation resulted in cure, and for herniae through the bony parts of the thoracic parietes this type of repair seems to be the most practicable.

The case recorded above is clearly of the consecutive type; eighteen months elapsed between the date of the accident and the appearance of the hernia. As a result of the chronic cough the scar tissue in the chest wall and pectoralis major yielded, allowing the hernia to appear. As far as the treatment is concerned the defect in the chest wall is rather large for satisfactory closure by means of an osteochondral flap; the hernia is controlled adequately and comfortably by the corset.

I am indebted to Mr. J. F. Dobson for permission to publish this case.

HAEMATURIA IN CHILDHOOD ASSOCIATED WITH ACUTE MASTOIDITIS

Mr. E. Carew-Shaw's note on the above subject (*Journal*, October 28th, 1933, p. 780) prompts me to record a somewhat similar case.

A. P., aged 6 years, first seen in the out-patient department of the Birmingham Children's Hospital in August, 1933, gave a history of pain in left ear for three weeks, and discharge from the left meatus for two weeks. On examination there was found to be a profuse discharge from the left meatus and also definite mastoid tenderness. The temperature was 99.6° F. A diagnosis of acute mastoiditis was made and the child admitted to hospital. The usual routine examination of the urine prior to operation was carried out, and definite haematuria was discovered (no previous history of this). The child was kept under observation for twenty-four hours, and it was then decided to operate. The haematuria and mastoid tenderness were still present, although the temperature was not quite so high as on admission. A Schwartz mastoid operation was performed, and within forty-eight hours there was a definite improvement in the urinary condition. Within five days the haematuria had completely disappeared. The child's condition was very satisfactory when he was discharged from hospital five weeks after admission.

This case confirms Mr. Carew-Shaw's conclusions that the haematuria was secondary to the mastoiditis, and that the presence of haematuria associated with mastoiditis is a very definite indication for early operation.

I am very much indebted to F. D. Marsh, F.R.C.S., for his courtesy in allowing me to report this case.

LAURA L. BATEMAN,
Resident Surgical Officer, The Children's
Hospital, Birmingham.

Reports of Societies

CONGENITAL AORTIC STENOSIS

At a meeting of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland, held on December 15th, 1933, with the president, Dr. W. J. Jessor, in the chair, Professor A. FRANCIS DIXON showed the heart of an infant in which there was considerable stenosis of the aorta proximal to its connexion with the ductus arteriosus. The ductus arteriosus was small and contracted. The right atrium was very large and the right ventricle formed by far the greater part of the heart. There was no interventricular communication, and the foramen ovale was small. The left atrium and the left ventricle were both very small. The right and left atrio-ventricular valves were normal. Macroscopically the stenosis appeared to be due to endarteritis. The specimen was obtained from a case which had been under the care of Dr. Collis.

Dr. W. R. COLLIS said he had seen this baby about five hours after it was born. The child had had a syncopal attack. There was no obvious murmur, and it was difficult to make out whether the heart was enlarged, what had actually caused the attack, and whether it was a case of congenital heart disease. A diagnosis of congenital heart disease was made, and in twenty-four hours time the child had another attack, and was admitted to hospital, where she died on the third day after admission. While in hospital she had attacks of "blueness," and became cyanosed, but in between the attacks she was a very good colour. It was interesting to note that, from the clinical point of view, there were two types of stenosis of the aorta, one in which the stenosis was proximal to the ductus arteriosus and the other in which it was distal to it.

The President said that it was very difficult to account for the attacks of "blueness" in this case. He wondered if there was any question of spasm of the pulmonary vessel which would account for them.

Reviews

"YEAR BOOK OF RADIOLOGY"

The *Year Book of Radiology, 1933*, by CHARLES A. WATERS and IRA I. KAPLAN, is assured of a warm welcome from the radiologists in this country. The first edition was published in 1932, and was an immediate success. It gave a concise yet complete account of all the principal advances in radiology that had occurred during the preceding fifteen years. It is not to be inferred, however, that the 1933 *Year Book* is merely a revised edition, for, although the design is similar, the work has been brought up to date, and a much more extensive investigation and abstracting of foreign literature undertaken. In order to make full use of the new edition it must be read in conjunction with the 1932 *Year Book*. It does, however, contain so much new material that by itself it will prove an invaluable addition to the library of all radiologists.

The work is divided into two parts: I, Radiological Diagnosis; II, Radiotherapeutics. In regard to the first, there are some who think that the limit of possibilities in radiological diagnosis has been reached, but each year there is something new to record in both technique and diagnosis. In the compilation of this book the radiological literature of all countries has been searched and abstracts made of all the important papers. The references are accurately given, so that when desired the original papers may be consulted. It is, of course, impossible to do more than indicate the main features of the work. All the systems of the body are dealt with, the osseous system being especially well done. Abstracts of papers dealing with bone changes in diseases of the endocrine glands, with xanthomatosis and other rare diseases of bone, will be found in this section. The illustrations are numerous, and placed in close relationship to the text—which is very helpful to the reader. Other chapters which deal with technique, history, teaching, and medico-legal matters are of great interest.

The second part of the *Year Book* opens with a general discussion on radiological physiology, biology, and physics, the views of many readers being given regarding the action of x rays and radium on living cells. The general considerations in radiotherapy are clearly stated, and a large section is devoted to the radiotherapeutic treatment of cancer. Abstracts of papers dealing with the relation of dosage to gene mutation rates are of great interest, and many papers give critical analyses of the results of radiotherapy. All the methods of irradiation are referred to, many of the papers laying particular stress on the underlying physical principles on which these methods are based. There is no doubt that, apart from malignant diseases, irradiation is being called for in an ever-increasing number of ailments. The reader will find the latest information, abstracted from the literature of all nations, assembled in the various sections into which Part II is divided. Some of these sections will be of particular interest to specialists other than radiologists—for example, radiation in dermatology, in ophthalmology, in mouth, nose, ear, and throat, in gynaecology, in neurology, and in genito-urinary conditions. One section which should appeal to all is that dealing with injuries in radiation therapy.

It should be noted that throughout this work the authors are not expressing their personal opinions, but are putting before the reader carefully compiled abstracts assembled on a definite plan, so that any subject can be readily referred to. There is an excellent index of both subject-matter and authors. The numerous illustrations

Year Book of Radiology, 1933. By C. A. Waters and I. I. Kaplan. Chicago: Year Book Publishers Inc. 1933. (Pp. 694; 780 figures. 75 dollars.)

are of first-class quality, as is also the print. It is obvious that no expense has been spared in the production of a work of reference which appeals not only to the radiologist but to specialists in many other branches of medicine.

LOCAL ANAESTHESIA*

Dr. ARTHUR E. HERTZLER's volume on *The Technic of Local Anaesthesia*² continues to be deservedly popular, as is evidenced by the publication of a fifth edition. The reasons for its popularity are not far to seek. It is simply written and easy to read, it is well supplied with excellent illustrations, and, above all, it shows itself to be the work of a practical man, who has acquired his knowledge and developed his technique in the course of extensive experience. Dr. Hertzler is not biased in his views as to the value of local anaesthesia. If general anaesthesia is the method of choice he has no hesitation in saying so. He states quite frankly that he has very little enthusiasm for the use of splanchnic block in abdominal surgery.

The introductory chapters deal with the various drugs which are commonly employed to produce local anaesthesia and the technique of administration. Sound advice is given with regard to the care of the patient, both before and during the operation. The author stresses the point that preliminary hypnotics should be given a full hour or two before operation if they are to exert their maximum benefit. He also advises the employment of gas and oxygen, with or without ether, as a supplement to local anaesthesia in certain cases. A chapter on spinal anaesthesia has been written by Dr. Arch. E. Spelman, who shows a marked preference for the use of novocain. The chapter might with advantage have contained some reference to the use of percaine, which has now passed beyond the initial experimental stage. We do not agree with Dr. Spelman when he states that spinal anaesthesia should never be given with the patient in the sitting position. There is also a short chapter written by Dr. Raymond F. Gard on intravenous anaesthesia, with particular reference to the use of sodium amytal.

Dr. Hertzler's book has been well produced, and is in no sense unwieldy. We can confidently recommend this very practical volume to those who are interested in the employment of local anaesthesia.

SURGICAL ASPECTS OF PULMONARY TUBERCULOSIS

A book combining the medical and surgical treatment of pulmonary tuberculosis,³ and written by one individual, should prove to be of considerable value, and the wide experience of the author, Mr. MORRISTON DAVIES, entitles him to cope efficiently with such a problem. From this point of view we regret that more of the personal results of the author are not included, rather than groups of results gathered from various foreign clinics, to illustrate the value of the different procedures advocated.

We agree with the view that early cauterization of adhesions is not advisable, as many of them disappear after continuance of the pneumothorax for three or four months; but the main and only real necessity for the operation—namely, the closure of cavities—hardly appears to be sufficiently stressed. The chapter on phrenicectomy is full, and few comments need be made, but the anaesthesia for the operation would appear to be unnecessarily widespread, and by the method advocated it entails the

presence of an extra assistant if many operations are performed successively. The value of the operation in relaxing adhesions holding out cavities during pneumothorax treatment as an alternative to cauterization could be added to the indications given. Thoracoplasty in various forms is widely discussed and described, and the modern view of the extensive but localized upper thoracoplasty is indicated. Many thoracic surgeons, however, will not support the author in the use of chloroform, a definite cardiac poison, as many of these patients have been subjected to a low-grade toxæmia, in some cases for years, before operation. Furthermore, the author states that heart failure is the commonest cause of death after thoracoplasty.

An account of the operation of scalenectomy is also given, and Mr. Morriston Davies records his results in eleven cases. The value of this operation is to be regarded as *sub judice* at the present time, and it is certainly doubtful if it will justify its use, particularly in view of the fact that it necessitates a major operative procedure entailing definite risks of its own and offering relatively minimal results. It is difficult to agree with the author that irrigation of the closed pleural cavity with Carrel-Dakin solution is of little value in tuberculous pleural effusions. Such irrigation will often permit complete re-expansion of the lung, a result particularly desirable when the original infection has been chiefly pleural rather than pulmonary. In primary pulmonary cases it is often inadvisable to attempt to get full re-expansion, because cavities previously healed may be reopened and the pulmonary lesion thereby reactivated.

The minor nature of these criticisms indicates that this book is of a high standard, and cannot fail to be of considerable value to all those interested in the modern treatment of pulmonary tuberculosis, whether from a medical or from a surgical standpoint.

ST. BARTHOLOMEW'S REPORTS

The *St. Bartholomew's Hospital Reports*⁴ are, next to those of Guy's Hospital, the oldest in London, and for sixty-six years have recorded the work of the oldest teaching hospital in the metropolis. Of the eleven chief articles in the current volume the first and the last are historical, on worthies of the staff, and the intervening nine give the results of investigations into the modern problems of medical science and practice. The first article is a sympathetic "In Memoriam" by Sir D'Arcy Power of his contemporary Richard Gill, a phenomenally brilliant student, who gave anaesthetics at the hospital for thirty-five years, and thus must have taught this subject to more medical men than has any other teacher. Otherwise Gill was a rather aloof, perhaps almost mysterious, personality mainly interested in economics, and the author of publications on free trade from as far back as 1887. This memoir gives a sketch of the life of a house-surgeon in 1880-1, the arduous duties being performed efficiently by Gill, but without arousing enthusiasm, perhaps because he was already engaged in thinking out the economic problems which occupied so much of his after-life. The history of anaesthetics at the hospital is also outlined, and shows that in 1875 an "administrator of chloroform" was for the first time appointed in the person of Joseph Mills, who was a good organizer, punctual, never perturbed, who hardly ever spoke, and who had only one other interest—namely, dancing. Gill was appointed his assistant in 1881, in 1893 his successor as "chief chloroformist," and wrote seven papers and a two-volume book on the subject. The other biographical article, the "Life and Works of Percivall Pott," by G. Marner Lloyd, is the Wix Prize

* *The Technic of Local Anaesthesia*. By Arthur E. Hertzler, A.M., M.D. Fifth edition. London: H. Kimpton. 1933. (Pp. 292; 148 figures. 25s. net.)

² *Pulmonary Tuberculosis*. By H. Morriston Davies, M.D., M.Ch., F.R.C.S. London: Cassell and Co., Ltd. 1933. (Pp. 464; 77 radiographic plates, 69 figures. 75s. 6d. net.)

⁴ *St. Bartholomew's Hospital Reports*, vol. LXVI. London: John Murray. 1933. (Pp. xxiv + 363; 49 illustrations. 21s.)

Essay for 1933, and more than justifies the establishment of such prizes.

An instructive symposium on sympathectomy is introduced by Mr. R. E. Norrish's demonstration at the hospital, before the Surgical Section of the Royal Society of Medicine, on the anatomy of the various parts of the sympathetic system, which is admirably illustrated by figures. This is followed by seven reports on the effects of this operation on cases of megacolon, hydro-ureter, Raynaud's disease, angina pectoris, chronic gastric ulcer, spasmodic dysmenorrhoea, and chronic arthritis. The complete recovery from a crippling arthritis of the right shoulder, wrist, and hand after removal of part of the inferior cervical sympathetic ganglion and the first dorsal ganglion is cautiously left open as either a *propter hoc* or a *post hoc* event. Mr. J. Beattie records three cases of the rare condition of injury of the lumbo-sacral cord during parturition. The health of the nurses serving their four-year indenture at the hospital during a recent period of years is considered by Dr. W. P. S. Branson, who shows that during their first year nurses are specially prone to sore throats, and that in 1931 the modest allowance of an apple a day cost the hospital £463. This is followed by Miss M. H. Hart's essay on pre-Reformation nurses in England, which was awarded the Nutting-Dock Prize. Dr. G. A. Harrison discusses the clinical chemistry of alkaptouria and melanogenuria, Dr. L. P. Garrod inhibitory selective culture media, Mr. H. J. Burrows' tissue culture in its relation to surgical pathology, and Dr. W. J. Oakley the blood urea clearance; these articles prove what an amount of valuable research work is going on at the great hospital of the City of London. Mention should also be made of Mr. Raven's account of the valuable work done by the Follow-up Department.

VARICOSE VEINS AND HAEMORRHOIDS

Under the title *Varicose Veins and Haemorrhoids and their Treatment*,¹ Dr. V. MEISEN has published his experimental and clinical studies in connexion with these two common disorders. To all who are acquainted with the Continental literature on these subjects Dr. Meisen's name needs no introduction, and in both subjects dealt with here he has had exceptional experience. The translation into English is the work of Dr. Hans Andersen, and it has been well carried out. A considerable portion of the book is naturally devoted to modern injection therapy, but the author has not fallen into the all too common error of many writers on these subjects of seeing in this particular form of treatment the beginning and the end of the treatment of varicose diseases.

The preliminary chapters deal with the anatomy and physiology of the venous system, and the disturbances of function which occur in association with the varicose state. As regards therapeutic injections, Dr. Meisen believes the ideal drug has yet to be found, and does not confine himself to the use of only one preparation. Glucose, glucose and sodium salicylate, sodium salicylate and sodium chloride, and 25 per cent. and 30 per cent. sodium salicylate all find a place in his armamentarium, though the real necessity for such a variety of drugs is not clearly described, nor are the indications for the use of each adequately dealt with. In connexion with the subject of recurrences of varicose veins after injection treatment Dr. Meisen quotes Svend Hansen's recent paper, in which a recurrence rate of some 25 per cent. was noted. It has to be remembered that varicose veins are invariably a progressive disorder, dependent

very largely on something inherent in the "soil," which injections will do nothing to eradicate, and recanalization can only be accurately determined in the case of veins which are easily chartable and recognizable. Undoubtedly many so-called recurrences are the result of incomplete injection treatment and too short a period of observation after treatment.

English readers of the book must be warned that the use of the word "phlebitis" is confined to deep phlebitis, or thrombosis of the femoral vein, and not as in this country for the designation of superficial phlebitis. This latter condition Dr. Meisen always refers to as thrombosis. Whether the distinction between thrombosis and phlebitis of a superficial varicose vein is often a practicable one is a moot point, but from the point of view of injection treatment it is advisable to regard all cases as potentially bacterial in origin.

A short chapter on the injection treatment of haemorrhoids is included, but this is not, on the whole, up to the level of the rest of the book, and no clear indications are given as to the limitations of injection treatment—a matter of considerable importance if the best results are to be obtained.

SPECTROSCOPY

*Spectroscopy in Science and Industry*² is the title of a small volume by Dr. JUDD LEWIS describing the principles on which spectroscopy has been applied to the elucidation of a great variety of problems. The delicacy of spectroscopic work in certain fields is well known, but it will be learnt with astonishment by many that morphine may be identified with certainty and the amount determined spectroscopically with a quantity of no more than one-hundredth of a milligram. Recent spectroscopic investigation appears to have cleared up the doubt affecting the absorption of aluminium by the human system. It has been found that blood normally contains less than one part in ten millions, and that the quantity rises to a maximum of about one part per million on the continued ingestion of an aluminium salt. Such a finding would be almost impossible by means of chemical reagents, but this result was accomplished spectroscopically with quantities of blood no greater than 1 c.cm. It appears that even a pathological condition of blood serum is distinguishable by the spectrometer. The volume describes the newest forms of apparatus used, and gives an outline of the methods by which these remarkable determinations have been accomplished.

Notes on Books

There must be many practitioners who, in spite of, or perhaps in consequence of, numerous discussions on the subject, have very vague opinions on the value of tuberculin in relation both to diagnosis and to treatment. In a short collection of papers³ by Dr. ROBERT CARSWELL, who has long cultivated a practical study of the subject, readers will find both information and guidance. Dr. Carswell has come to some very definite conclusions, and he produces the evidence on which these rest. Thus he is satisfied that by the use of tuberculin timely intimation of the existence of tuberculosis can be obtained even when all other methods of examination have proved negative; and similarly, that, by the same agent, cure of the disease in the initial stage is possible. In short, on the latter point, he holds to the original teaching of Koch, that by a proper method of immunization incipient tuberculosis can be cured with certainty. The doses in which the remedy should be used, the methods employed, and the

¹ *Varicose Veins and Haemorrhoids and their Treatment*. By V. MEISEN, M.D., Copenhagen. Translated by H. ANDERSEN, M.D., Copenhagen. London: Medical Book Co. Ltd. 1933. (Pp. vi + 244. 4s. 6d.)

² *Spectroscopy in Science and Industry*. By S. JUDD LEWIS, Ph.D., F.R.C., London and Glasgow. London and San, Cal. P.O. (Pp. vi + 244. 4s. 6d.)

³ *Papers on Tuberculosis*. By ROBERT CARSWELL, M.A., M.B., Ch.B. London: The Hutchinson Press. 1933. (Pp. 17.)

indications, Dr. Carswell describes, as he has learned them in his own practice, and the manner in which he presents his argument claims an attentive airing.

Who's Who for 1934¹ contains some 40,000 biographical sketches neatly printed on 3,650 double-columned pages. It is no small achievement on the part of the publishers, Messrs. A. and C. Black, Ltd., to assemble so vast an array of personal facts within the covers of a thick but not unwieldy volume weighing under 4½ lb. As a work of reference it is invaluable in newspaper offices, libraries, clubs, etc.; and to some people with time on their hands it is a never-failing quarry of unconscious humour. Here and there will be found, even on casual inspection, a "living notability"—the phrase is Messrs. Black's, not ours—with a pretty turn for exhibitionism.

It is pleasant to note what is on the whole a progressive improvement in the textbooks on science subjects which are intended for use in elementary schools. Miss LIESE KNIGHT, the head mistress of the Marlborough "C.C. Girls' School, Chelsea, should know what to provide, and her recent contribution—*The Golden Science Series*,² Book I—may be welcomed. It consists of a number of excellent chapters for seasonal nature study

Preparations and Appliances

CATGUT TUBE FORCEPS

Dr. JOHN W. STRETTON, F.R.C.S. (Dudley), writes:

These forceps—the Guest Hospital catgut tube forceps—have been designed for lifting cylindrical glass tubes containing catgut. The catgut tubes, submerged in antiseptic fluid, stand vertically in glass jars. The jaws of the forceps are

curved so that they partly encircle the catgut tube, and thus grasp the tube securely.

I am indebted to those of the Guest Hospital personnel and to Messrs. Arnold and Sons (John Bell and Croyden), 50-52, Wigmore Street, London, W.1, who assisted to bring my idea to a practical conclusion.

A MASK ATTACHMENT FOR ADMINISTRATION OF CHLOROFORM CAPSULES IN LABOUR

Dr. J. MARSHALL SCOTT (Exeter) writes: During the past fifteen months I have had considerable experience of the administration of chloroform capsules to women in labour. The usual method of using these has been to break a capsule at the onset of a uterine contraction, the broken capsule being then tucked between one of the struts and the gauze covering a Schimmelbusch mask, which is then applied to the patient's face. Two objections to this practice have been observed. (1) Occasionally by the time the capsule is broken—some are quite difficult to break with the fingers—and tucked inside the mask the worst part of the pain may be over. (2) With the movements of the patient's head during a uterine contraction the capsule is liable to fall out of its position.

To obviate these difficulties and to facilitate the administration of capsules, I have had made a small attachment which

fits inside the Schimmelbusch mask. A small metal plate is firmly attached half-way up one of the lateral struts of the mask by means of a screw. Projecting into the mask and fixed to each end of the base plates are two spring clips, into which the chloroform capsule is passed in the period between the pains. As a pain commences the capsule is pressed by the finger against a small wedge fixed to the base plate, and

The second edition of CALKINS's *Biology of the Protozoa*¹ shows considerable alterations from the first, although the main concept of a changing organization brought about by continued metabolism has been retained. It has been strengthened by a considerable rearrangement of the chapters, and by the addition of a special chapter on parasitism and disease. Although the whole volume is *professedly* biological in its outlook, there is included, as the final four chapters, an account of the special morphology and taxonomy of the main groups of the protozoa. The volume is more interesting to biologists than to medical men. It remains an excellent introduction to the phenomena of cell division, maturity, sex, fertilization, and senescence, as well as to the general physiology of the protozoa.

¹ *The Biology of the Protozoa*. By G. N. Calkins. Second edition. London: Baillière, Tindall and Cox. 1933. (Pp. 607; 2 plates, 223 figures. 37s. 6d.)

is readily broken. When the capsule is spent it is simply pulled out and replaced by a fresh one in readiness for the next pain.

The attachment has been in use in the maternity department of the North Middlesex County Hospital, and has proved most satisfactory. The capsule holder has been made for me by Messrs. Allen and Hanburys Ltd., to whom I am indebted for valuable suggestions and for the careful way in which they have carried out my instructions.

VITAMIN C: ASCORBIC ACID

As already mentioned in this column there is evidence to show that the antiscorbutic properties of fresh fruit and vegetables are due to the presence of "hexuronic acid," first isolated by Szent-Györgyi and recently renamed "ascorbic acid." The acid has been isolated from oranges, lemons, cabbages, and other vegetable sources, and also from the cortex of the suprarenal gland. It has been supplied for research purposes by Messrs. Burroughs Wellcome and Co. for more than a year, and is now issued as "tabloid" ascorbic acid, 0.005 gram, each product being equivalent in vitamin C activity to two teaspoonsful of freshly expressed orange juice. This is the second pure crystalline vitamin to be issued as a "tabloid" product, vitamin D having been issued for some years, first as "tabloid" irradiated ergosterol and now as "tabloid" calciferol.

SATURDAY, JANUARY 13th, 1934

RADIUM AND RADIATION THERAPY

During the last months of 1933 no fewer than three reports were issued by responsible authorities on the subject of radium and radiation therapy. Of these the first to appear was that of the Radium Commission, which has already been reviewed in these columns. The next was that of the Medical Research Council, and an interesting feature of both is the importance they attach to research work and to the provision of facilities for carrying it out. The third report is that of the committee set up by the Section of Radiology of the Royal Society of Medicine, which appeared as a supplement to the November number of that Society's *Proceedings*, and from the point of view of the majority of our readers it is perhaps the most interesting of the three. The recommendations of this report include the establishment of a special radiotherapeutic hospital in or near London and the appointment in connexion therewith of a director having a "wide experience of x-ray and radium therapy." How far it may be desirable to equip new institutions, and thereby to add to the already vast expenditure on bricks and mortar, may be a matter of opinion. Many consider that readjustment of the arrangements of existing institutions would satisfactorily meet the case; but on the second recommendation there can be no difference of opinion among those best qualified to express an authoritative view upon the subject. It is indeed matter of common knowledge among radiologists that it is high time for x-ray therapy and radium therapy to take their proper place in this country. There has been—and in too many places there still is—a tendency to regard radiation therapy as an adjunct to surgery. In plain words, the surgeon is looked upon as the predominant partner and the radiologist as an assistant to carry out such therapeutic measures as may be "desired" by the surgeon. Such a view expresses a fallacious estimate of the relative positions of radiologist and surgeon in this matter. If radium therapy merely consisted in the suitable disposal of a series of platinum needles the problem would obviously be a purely surgical one. This is, however, by no means the case; the platinum needles contain the radioactive material which is the source of the radiation intended to produce certain therapeutic effects. The part of the surgeon is therefore secondary to meeting the requirements of the radiological experts. The manipulative skill necessary for the efficient carrying out of the "surgery of access" is in no way depreciated by this view of the matter; but the situation is one which must be grasped.

A brief glance at the committee's report will show how different are the conditions at the most important Continental and American centres: indeed, in this country we are still in a transition stage which has been long passed in those countries where radiotherapy has reached its proper position. Too much attention is paid here to merely empirical clinical results, and far too little to the fundamental problems of experimental radiology. It is not asking too much to urge that surgeons wishing to specialize in radium therapy should as a preliminary obtain a diploma in radiology. X-ray therapy and radium therapy are closely associated, so closely indeed that the intelligent study and practice of the one demands a competent knowledge of the other. On the Continent and in America fully equipped high-voltage x-ray units are recognized as forming an integral part of any well-run radium department. In this respect we are woefully behind them: there does not seem so much difficulty in raising funds for the establishment of elaborate x-ray diagnostic departments, but in the majority of our radium centres the x-ray therapeutic equipment falls far below even the minimum requirements. X-ray and radium therapy are complementary, and, that being the case, it is obvious that the director of such work should be one having a wide knowledge not only of the clinical but of the theoretical side of the subject. Radiological, physical, and pathological knowledge must come first. Undoubtedly in the past difficulties have arisen which have placed x-ray and radium therapists in awkward and invidious positions. The nature of his work makes it necessary that the director should be a whole-time salaried official. No less essential is his recognition as the full equal of his honorary colleagues on the hospital staff, and in his own department as definitely holding the premier place.

Admittedly very excellent clinical results have attended the use of radium in the past; it will, however, be found that the best results have been obtained in just those places where the collaboration between radiologist and surgeon has been the most complete, and where the dominant influence has been scientific. It is absurd to suppose that an adequate knowledge of radium therapy can be acquired by the haphazard methods which are even now still only too frequent in this country, where attendance at a brief course of instruction supplemented by a few visits to Continental or American centres seems to constitute the utmost that some consider necessary. The subject is one that demands a life study, and for its efficient therapeutic application a knowledge of physics, pathology, and of the mode of action of radiations upon living tissues is essential. A large amount of most valuable work upon experimental radiology has been done in this country which is but too little known outside the circle of immediate workers. It is this work which provides the basis for an adequate system of x-ray and radium

therapy. Certainly therapeutic and experimental departments should work in the closest collaboration, with specialists in physics, pathology, and such other branches of science as may be found necessary. It should also be remembered that funds are needed for the efficient carrying out of this experimental work: the clinician is able to secure his maintenance while gaining experience; the research worker, on the other hand, is dependent upon endowments. For this reason it seems open to question whether it would be well to embark upon further extensive building operations with the consequent expense of lay officials such as clerks and secretaries in greater or less number.

There are signs in at least some of our great institutions that radiology is at last beginning to come into its own instead of being regarded as a mere accessory to other therapeutic methods, and but too often as a last resort when other methods have failed. The situation has to be faced; it is therefore best to face it boldly and at once by placing radiation therapy upon the basis to which it is now entitled.

MEDICAL PROBLEMS OF WINTER

The manifold problems which confront medical practitioners at all times of the year become particularly difficult during the cold season, since the co-operation which he has always to stimulate in the organism is especially difficult to invoke at this time. The important influences exerted by climate and weather on the general tendency to develop infections have induced our contemporary the *Deutsche medizinische Wochenschrift* (December 8th, 1933) to devote an entire issue to the consideration of the problems involved. The matters dealt with are very wide in scope, but we will refer to only a few of the more outstanding of them.

The liability of certain chronic affections to become aggravated in winter is well known, and increased care is necessary, particularly in such cases as prostatitis, cystitis, and any other conditions involving the urogenital tract. Patients with chronic nephritis tend to lose more urinary protein in winter, and diabetics are not infrequently found to require an increase in both diet and insulin. The actual exposure of a healthy subject to cold is not in itself sufficient to initiate disease: indeed, it was the experience of the German Himalayan expedition that, whereas all the members of the party were quite well at a temperature of $-20^{\circ}\text{C}.$, a sudden change in the weather with a rise in temperature to $0^{\circ}\text{C}.$ was followed by a development of catarrh of the upper respiratory passages. The tendency, however, of parents to "harden" the child by such draconic measures as sleeping close to an open window, cold douches, or wearing very short socks is not to be encouraged where the climate is damp or when the child complains of cold. On the other hand, heating the bedroom is not so wise a procedure as using a hot-water bottle, and if a child complains of cold feet it is usually sufficient to bathe them in hot and cold

water alternately, and then rub them vigorously with a warm towel. The addition of yolk of egg and an increased amount of butter to the winter diet of the child, and also a small amount of cod-liver oil, is recommended by Rietschel. "High sun" treatment, if employed for ailing children in winter, should be carried out in the home of the patient, and it is well to remember that infections may follow if great care is not exercised in controlling the dose, etc.

The problem of winter clothes is an old one, and, however scientific the recommendations of the medical adviser may be, many patients continue to load themselves with enormously thick and impervious coverings. The important thing in keeping heat in is the air content of the clothing, and garments of loose, light material fulfil this object better than a series of layers of heavy stuffs. A properly chosen winter garment has a lower specific gravity than a summer garment, so that, in spite of the greater actual bulk of the former, its total weight does not much exceed that of the latter. Recent work has also shown that the common practice of adding an undergarment during the winter is of little or no value in helping to retain heat, but it does undoubtedly prevent the sudden chill which might take place in passing from warm rooms to the cold outer air. The "airiness" of clothing is also very important, since the comfort of the body depends to a large extent upon a free exchange of air, allowing evaporation to take place easily and preventing undue condensation of perspiration in the garments. It is interesting to recall that fur, containing 95 per cent. of air, is the most efficient of materials for retention of heat, but its impermeability to water vapour makes it a poor covering if any considerable amount of perspiration is produced, as, for example, during hard work.

The change in the consistency of certain foods (for example, vegetables) which occurs in winter may bring certain ills in its train. In contrast to the delicate vegetables obtained in summer, winter vegetables are coarser and richer in cellulose, and hence more difficult to digest. This makes itself felt in vagotonic subjects, who, as a result of such food, develop intestinal pain and spasm of the colon. Similarly, in cases of cholangiopathy, winter conditions may bring about an aggravation of symptoms. The question of vitamin deficiency in winter is less serious nowadays than it used to be, many alternative active preparations being available in concentrated form. Prophylaxis against winter ills is a very difficult matter, and it is not at all clear that the pathologist's vaccines, or the non-specific injections of protein, lipoids, or blood, have much to recommend them in the prevention of the common winter infections. General principles still seem to be the best, such as hygiene of the mouth and pharynx, and in some cases "high sun" treatment. Van den Velden recommends diaphoresis, carefully carried out so that no ill effects follow, as a useful prophylactic measure. The decision as to the necessity for change of climate must remain a matter dependent upon individual conditions.

A TREATMENT OF CANCER

For some twenty-odd years Professor Fichera¹ of Milan has been carrying on research into the growth-promoting and growth-inhibiting properties of various organs of the body. He found that tumours implanted into various organs of the rat grew at different rates. In some (for example, the testis and the ovary) the tumours grew rapidly. In others (for example, the spleen) growth was inhibited. He found that the growth-inhibiting organs, *par excellence*, were the spleen, the thymus, and the bone marrow—tissues which house the reticulo-endothelial system. At the International Cancer Congress, held in Madrid in October, 1933, Fichera read a paper on the chemotherapy of cancer, in which he stated that he had, since 1930, treated 300 cases of cancer with injections of extracts of what he calls "antiblastic" organs (spleen, thymus, lymph gland, and bone marrow). A hundred of these cases were inoperable, and these received Fichera's "biological therapy" only. The remedy is prepared as follows. The thymus, spleen, lymph glands, and bone marrow of freshly killed calves are extracted in saline in the presence of thymol and toluol in an incubator from a week to two months. The dosage is 1 c.cm. twice weekly (intramuscular or intravenous injections), continued for several months. In 9 per cent. of his 100 cases the tumour disappeared (in two cases, a three-years' cure, and in seven a two-years' cure), while in 8 per cent. there was partial regression of the tumour or the condition remained stationary. He also claims improvement in another twenty cases. Forty of the patients died, and in twenty the tumour was advancing. In an earlier paper,² which must have been prepared for final publication about two years before the Madrid conference, Fichera stated that he had obtained improvement in twenty-eight patients out of fifty-five who had received biological therapy only. It is difficult, with existing data, to assess the value of this form of treatment. The number of cases treated by biological therapy alone is small, the successful results claimed are relatively few, the time that has elapsed (three years) is too short to state unequivocally that the "cures" obtained will be permanent. In his publications Fichera has given only very scanty clinical details of his cases. It should be understood that no claim is made that the method of treatment ought to supplant that by the recognized therapeutic measures of surgery, x rays, and radium.

PATHOLOGICAL EFFECTS OF LIGHT

Much has been written on the benefits of sunlight. It remains for Dr. Jausion and Dr. Pagès to write on the diseases caused by light and their treatment.³ They describe, in the first place, the physiological effects of light upon the skin, and the protective mechanisms which produce the pigmentation and hypertrophy of the horny layers, which are universally recognized. Subsequently they go on to enumerate various compounds that render the animal organism sensitive to the action of light, of which the most important are the various porphyrias occurring in nature, and drugs,

such as sulphonal, which determine their production in the body. They themselves have particularly investigated the action of substances derived from acridine, especially gonacrine. This body, if injected subcutaneously, renders the skin liable to develop dermatitis when exposed to strong light, and the dermatitis is speedily followed by pigmentation and later by hypertrichosis. Jausion and Pagès have taken advantage of these properties of gonacrine in the treatment of leucoderma or vitiligo. First of all they administer a series of injections and then subject the patient to a course of light baths, either artificial or natural. He then has an intravenous injection of a mixture containing hyposulphite of soda and a minute percentage of pilocarpine and methylene-blue, and is subjected to treatment with infra-red rays. As a result of this procedure, it is said that both the pale and the hyperpigmented patches, which are characteristic of the disease, tend to approximate to the same tint. The authors, while confessing that the result is not perfect, claim that their patients gain permanent benefit. They have some interesting observations to make. They have been successful in relieving two patients—subjects of hydroa vacciniforme—by a combined treatment with resorcin and with gonacrine, which is directed towards diminishing the vulnerability of the skin to light by increasing its capacity for producing pigment. Whether this procedure is practicable for clinical purposes or not is still doubtful, but the authors are trying to work on scientific lines, and those who are interested in the pathological effects of light will do well to note their experiences.

MEDICAL HISTORY WITH PRICKLES

The issue of the *Canadian Medical Association Journal* for December, 1933, includes a lecture on the reading of history, given to the College of Physicians of Philadelphia by Sir Andrew Macphail, professor of the history of medicine, McGill University, Montreal. No abstract could convey the vintage flavour of this essay; it must be read as a whole. Those who remember Sir Andrew Macphail's contributions to our pages will expect to find here something out of the common, and they will not be disappointed. They will read in the opening paragraphs such phrases as these: "History is not a series of falsities agreed upon. Rather, it is two series of alternatives or contradictions, with their respective protagonists at the head. . . . And the historian is a man; his history arises from his heart; it mounts to his head, and trickles through his fingers upon the written or printed page. Before we can accept as true what he writes, we must know something of his heart, head, and hand. That is the task of modern historical criticism; and the critics are now in full cry, with a result that is devastating of traditional opinions. The history of medicine has been too long immune from this critical process." And again, further on: "Medicine is a large part of life; and the history of medicine is a large part, possibly the largest, of the history of life. Human activity is governed by sickness and health." These last two sentences sound the keynote of the lecture, and Sir Andrew develops his theme with a dry and sometimes mordant humour, which will not be to everyone's liking but makes first-rate reading. He tells us that the widest gulf between

¹ *Lancet*, 1933, 1, 1202.² *Lancet*, 1931, 1, 1202.³ *Med. Hist. J. (Lancet)*, 1933, 1, 1202.

of H. Pagès, Paris, Masson et Co. (45 pages).

historians is religious belief. "This bigotry has vitiated the whole history of medicine too. In general it takes the form of a charge that the Church has been a consistent enemy of science as a whole and of medicine in particular." But since the term "Church" is here used to mean equally "the Churches that had their respective sects in Rome and in Geneva," he picks out from each side a few cases to illustrate some of the main sources of such error in reading the history of medicine. A point he insists on throughout is that history must be studied in the light of the temper and beliefs of the period. Here is a prickly passage for authors and editors: "We must read and judge ancient medical journalism as we read and judge our own. There were advertisers in those days, but their methods were less refined than ours. And yet, our journals contain the outpouring of laboratory note-books, papers describing not what the writer has done, but suggesting what he proposes to do, preliminary deliverances, so that a possible competitor may be forestalled." Summing up the present period Sir Andrew Macphail hazards a guess that it will be classified as that of the iatro-biochemists; future historians, he thinks, will fail to understand the medical writing of to-day, and may well doubt if we understood one another, for our observation has outrun our power of expression, and we coin new words as we go along. But there is one movement that earns his commendation. He sees in the most modern medicine a definite tendency to bring the theories begotten in the laboratory to the test of the bedside. As we gather it, the general message of this provocative lecture is twofold. Wrong opinions of the past breed wrong opinions of the present. It is for the doctors of to-day, with their better knowledge of Nature's ways in collateral fields of science, to make better use of the method bequeathed to them by the greatest physicians of all the ages, who looked upon disease with fresh minds unclouded by tradition or authority.

VACCINATION AGAINST TYPHUS FEVER

R. Weigl has lately described a vaccine successfully employed during the last three years in the prophylaxis of typhus fever.¹ It is prepared from the intestinal contents of lice. The lice are infected by rectal inoculation with rickettsia. The organisms multiply in the intestine, reaching their maximum numbers in a week. The intestine is removed and ground up in phenolized water. The resulting product constitutes the vaccine. Up to the present over 6,000 vaccinations have been performed, and the results appear to be very satisfactory. Its use has been restricted mainly to the medical personnel working in typhus-stricken areas and to contacts of known cases. Of 2,755 persons in Poland who received three doses—corresponding to the intestinal contents of 120 to 175 lice—not a single one developed typhus fever. On the other hand, during the course of the vaccinations about 0.5 per cent. of those inoculated developed typhus, though in a more benign form than usual. They were apparently in the incubation period at the time of inoculation. This and other evidence suggests that full immunity is not established till a little while after the course of vaccination is completed.

¹ Arch. de l'Inst. Pasteur de Tunis, November, 1933.

REFUGEE DOCTORS IN FRANCE

On April 21st, 1933, the Armbruster law governing the practice of medicine in France was promulgated. According to the first article, no one may practise medicine in France without possessing a French State diploma of medicine or being a French subject. This law, not being retrospective, does not penalize foreigners hitherto entitled to practise in France, but it is an insuperable obstacle to newcomers, not least to the refugee Jew from Germany. The executive committee of the *Confédération des Syndicats Médicaux Français* adopted last April a resolution expressing indignation against the "veritable persecutions of which certain German doctors are at present the victims," and insisting on the right every civilized country enjoys of freedom of choice between doctor and patient. In the presence of the Armbruster law and the crying need for its enforcement owing to the congestion in the ranks of the medical profession, this resolution must, of course, be taken as a Platonic gesture and nothing more. It would, however, be unfair to suggest that French hospitality is limited to passionate declarations of fraternal solidarity. Here and there openings are being found for individuals; and, at the Pasteur Institute, one of Calmette's latest administrative measures was to provide elbow-room for half a score of German doctors expelled from their own country on account of their Semitic ancestry.

BIRTH CONTROL CLINICS

Two of the more important of the societies established a few years ago to promote contraception among those in need of it have recently issued their annual reports for the year 1932-3—the National Birth Control Association (26, Eccleston Street, S.W.1) and the Society for the Provision of Birth Control Clinics (153A, East Street, Walworth Road, S.E.17). Each of them records definite progress for the cause which they represent. New clinics have been established, and most of those previously in being have shown increased activity. It appears that the number of local authorities known to have taken some action in this field has increased to seventy-three, as compared with forty-seven a year ago. The action which such authorities can take is, however, restricted in character and extent by a memorandum of the Ministry of Health, and it is claimed that there is great need for a less strict interpretation of these limiting regulations and for a widening of the sphere of action permitted. This may well be true, but any considerable movement in that direction on the part of the Ministry would arouse active opposition in some quarters and create difficulties in a good many areas. If only for tactical reasons it might be advantageous to consider extension in another direction, the need for which must surely make itself evident from time to time. There are married women of the poorer classes who want guidance not as to how they can best reduce their liability to become pregnant, but how, if possible, they may overcome the sterility which distresses them. Ought not the staffs of clinics, especially of those established or aided by national or municipal funds, to be as ready to help the one woman as the other? A "women's welfare clinic," comprehending both functions though not in equal measure, might be more easily tolerated by some people than the restricted

service now known as "birth control clinics." The National Birth Control Association has incorporated the very useful Birth Control Investigation Committee, which has done, and is doing, good work under the chairmanship of Sir Humphry Rolleston. The report states that "the work of this committee has proceeded satisfactorily" and indicates the nature of some recent researches conducted under its auspices. It was a pleasure in noticing a year ago the last report of the Society for the Provision of Birth Control Clinics to give an appreciative recognition of the special report by the medical officers of the Walworth Women's Welfare Centre. This year their report is on equally practical and sensible lines, but is not so striking, as it for the most part merely repeats and confirms the findings that emerged from the experience of the previous year. It is interesting, however, to note that the unfavourable opinions then expressed about the Grafenberg intrauterine ring and the stem (utero-vaginal) pessary have been confirmed, and that "of ninety-seven patients who ceased to practise birth control because they wished for a child, ninety-six became pregnant and had their babies." It is still too early to be certain of such a universal negative proposition as that the practice of contraception has no ill effects from the medical point of view; but evidence is gradually accumulating to show that sterility is not liable to be produced by any reputable methods.

THE PUBLIC HEALTH OF DENMARK

Last year a lecture was given by special invitation in Paris by Professor Madsen, director of the State Serum Institution in Copenhagen. This lecture, published in *Revue d'Hygiène et de Médecine Préventive* for November, shows that it is not by fortuitous circumstances, but by organization and centralization, that Denmark now has a lower tuberculosis death rate than any other country in Europe, and has achieved many other important advances in public health. The State Serum Institute centralizes the epidemiological work of the whole country to such a degree that practically every sample of pus, blood, etc., requiring a special examination finds its way to the Institute. Thanks to a grant from the Rockefeller Foundation, the Institute is able to send out as field workers specialists in public health fully equipped to investigate epidemics on the spot and in their earliest phases. The campaign against typhoid is so efficiently organized that at the present time no convalescent is allowed to leave hospital without a series of bacteriological examinations having been made of his stools, etc. If they continue to harbour the typhoid bacillus, and the convalescent cannot remain longer in hospital, the medical officer of health of the district to which he returns is notified in order that the necessary measures may be taken. Such a carrier is not allowed to handle food, particularly milk. If necessary he is given compensation. The Institute keeps an up-to-date record of all these carriers, whose change of address is promptly reported to the local medical officer of health. Owing to these and other public health measures, the incidence of typhoid in Denmark has dwindled from 40 per 10,000 inhabitants some forty years ago to 0.2 in 1930. In 1931 there were only eighty cases of typhoid in the whole country, whereas the number of registered carriers was 100.

Another field in which a vigorous campaign has yielded remarkable results concerns whooping-cough, whose death rate is apt to exceed that of diphtheria, scarlet fever, measles, poliomyelitis, and meningitis combined. The Institute has taken an active part in ensuring early diagnosis and effective vaccine treatment, and this has done much to reduce the mortality from whooping-cough. Other, and sometimes similar, measures have been taken with all the important infectious diseases. In the period 1890-9 every fifth death (20.5 per cent.) in Denmark was due to some epidemic disease. In 1930 this ratio had fallen to 6 per cent. During the same interval the tuberculosis death rate has changed its place on the list from the second to the seventh, by falling from 14 to 6.8 per cent. There is now one hospital bed for epidemic diseases for every 1,000 inhabitants—a provision which, with modern means of transport, ensures prompt isolation everywhere in Denmark. In two sentences Professor Madsen summarizes one of the most important changes in medicine in our time: "It is interesting to note that one has less and less recourse to disinfection. It is infinitely more important for the general practitioner and the medical officer of health to employ all possible means in tracking down the centre of infection (water, milk, another case of the disease, or a carrier) as soon as a case of infectious disease is discovered."

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* and *Epitome* have been prepared and will be ready shortly; they will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or all of the indexes can obtain what he wants, post free, by sending a post-card notifying his desire to the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

The biennial Huxley Lecture, on recent advances in science in their relation to practical medicine, will be delivered by Professor Julian S. Huxley at Charing Cross Hospital Medical School on Wednesday, January 24th, at 5 p.m. His subject will be "Embryology as an Experimental Science," and the chair will be taken by Dr. Gordon M. Holmes, F.R.S. Admission free, by ticket to be obtained from the dean of the Medical School, Chandos Street, W.C.2.

Since the retirement of Sir George Berry from the House of Commons in 1931, the combined Scottish Universities constituency has been without medical representation in Parliament. The recent death of Mr. D. M. Cowan, M.P., creates a vacancy which it is to be hoped will be filled by the nomination and election of a member of the medical profession.

We regret to announce the death of Mr. J. B. Lawford, LL.D., F.R.C.S., consulting ophthalmic surgeon to St. Thomas's Hospital, consulting surgeon to the Royal London Ophthalmic Hospital, Moorfields, and past president of the Ophthalmological Society of the United Kingdom.

MATERNAL AND FOETAL MORTALITY

AN AMERICAN REPORT

The White House Conference on Child Health and Protection, organized by President Hoover in 1930, has already published a number of valuable reports, but few can have possessed greater interest for the English reader than does the report of the Subcommittee on the Factors and Causes of Foetal and Maternal Morbidity and Mortality, of which Professor Ehrenfest of St. Louis was the chairman.¹ The subcommittee consisted of thirty-five members, representing all the most important medical centres in the United States; the authoritative character of its pronouncements is thus assured. The report consists of twenty-three articles (or reports as they are called in the text), each dealing with a specific subject. Most of the articles are written by obstetric teachers, but the admirable and comprehensive report on heart disease and pregnancy is from the pen of Dr. William W. Herrick, professor of clinical medicine in Columbia University. The article on parasitic infections in pregnancy is the joint work of a professor of obstetrics and a professor of parasitology in New Orleans.

Generally speaking, the articles all show evidence of careful preparation and wide reading; one important article concludes with a bibliography of sixty-one references. Instances of overlapping are rare, and it is clear that collaboration among the contributors has been well maintained. The common aim has been to deal with "factors and causes" as they exist in the U.S.A. American conditions are of course complicated by the existence on the one hand of a large negro population, and on the other of large sparsely populated areas in which medical services are deficient. This must be borne in mind in considering the high rate of maternal mortality with which the United States as a whole have to deal; this stands at about 6.5 per 1,000 live births, and showed no appreciable diminution in the period 1915 to 1929. Dr. Ehrenfest, in his summary, draws attention to the high rate of foetal, maternal, and infant mortality among the negroes, and attributes it to: (1) the relative frequency of contracted pelvis, (2) the high incidence of venereal disease, and (3) the "utter ignorance of the first principles of hygiene and of the care and nourishment of the infant." In sharp contrast stands the case of the Chinese in San Francisco, where "a thorough and competent survey" shows that mortality of both mothers and babies "compares most favourably with that reported for the entire city" (p. 21). No European country has comparable difficulties to face, and we shall watch with sympathetic interest the result of the strenuous efforts now being put forth by our American colleagues to deal with their exceptionally complex problem.

PULMONARY TUBERCULOSIS IN PREGNANCY

It is impossible within the limits of this review to do more than select for notice one or two of the larger subjects dealt with in the report. The articles on diseases of the endocrines during pregnancy will be welcomed for its clear statement of the present phase of the constantly changing picture of the endocrine functions. It is written by Professor Robert A. Mussy, and well maintains the reputation of the famous Mayo Clinic. The article on pulmonary tuberculosis in pregnancy, by Professor Otto Schwarz, reveals the fact that "the care given to pregnant tuberculous women in the U.S.A. is very much less than that accorded to non-pregnant tuberculous women." This unfortunate defect of organization, from

which we in this country are not free, appears to be common to all countries. The city of St. Louis has organized a maternity department in one of its sanatoria where women can stay throughout pregnancy and labour, and we learn from Professor Schwarz that a sanatorium near Dresden is building a separate division for the same purpose. Other countries will no doubt, in time, follow the example thus set. The best analysis of the results of cases of tuberculosis and pregnancy is to be found not in this article, but in another on fever in the puerperium, by Professor Caldwell of New York City. Here, in a series of 410 cases, it is shown that improvement in the mother's condition during pregnancy occurred in a large proportion of the "slight" cases, in a considerable proportion of the "mild" cases, and even in a small proportion of the "advanced" cases. The author's view is that it is "not the baby in the uterus but the baby in the home" which seriously endangers the life of the mother, through extra work, worry, and loss of rest. American practice is to forbid pregnancy in all cases of active tuberculosis for the reasons just stated, and for the further reason that post-natal infection of the child is almost certain to occur (p. 76). Early therapeutic abortion is accordingly advised in cases of active disease; in all other circumstances abortion is discouraged.

OPERATIVE DELIVERIES

The author of the article on forceps and Caesarean section, Professor E. D. Plass of Iowa City, draws attention to the fact that in the period 1915 to 1929 the neonatal death rate in the U.S.A. from birth injuries has risen from 3.9 to 5.5 per 1,000 births. German writers have recorded a similar tendency, and there can be little doubt that the great increase in operative deliveries which has characterized obstetric practice generally during the last fifteen years supplies the explanation of this increased loss of infant life. The author, in his review of the conditions which have led to the great increase in operative deliveries, particularly deplors the "exaggerated idea of the value of the infant's life in comparison with that of the mother" which is now in vogue. It is staggering to read that there are "a few clinics in this country [U.S.A.] in which the application of forceps is routine except when a precipitate delivery interferes with the obstetrician's plans" (p. 230). There is a type of operation known as "convenience forceps" which is extensively employed by those affected by the "operative furor," many of whom have come to regard "any variation in the foetal heart tones" as an indication for extraction by forceps. That great divergencies in practice occur is clear from the figures given, which show that in the special hospitals the forceps rate varied from 3.8 per cent. to 50.4 per cent., while in other hospitals it varied from 0.5 per cent. to 81 per cent. In Professor Plass's view a forceps rate of over 5 per cent. savours of meddlesome midwifery.

In discussing Caesarean section the author deplors the fact that "the range of employment of this operation has been extended until it includes every imaginable complication of pregnancy and labour," and yet it has "the highest mortality of any delivery operation." Figures obtained from hospitals in important centres of different States show a case mortality varying from 4.2 per cent. in Los Angeles to 16.1 per cent. in New Orleans. From another American city comes the report that over a certain period fifty-one Caesarean sections performed by general practitioners or surgeons resulted in a maternal mortality of 33 per cent., while fifty-six operations by obstetricians in the same period yielded a mortality rate of only 1.8 per cent. These figures, which could probably be paralleled in other countries, form a striking illustration of the results which may ensue when men of less

¹ *Foetal, New-Born and Maternal Morbidity and Mortality*. A publication of the White House Conference on Child Health and Protection, London. D. Appleton Century Co. 1933 (12s. 6d. net.)

skill and experience attempt to follow the example set by obstetricians. They also invite inquiry whether the special hospitals have duly weighed their responsibility in setting up an example which will probably be followed by all practitioners who desire to be "up to date"! The major operations of midwifery must often fall to practitioners whose experience of them is small, and in whose hands the operation risk will consequently be greater than in the hands of the specialist. It is therefore of the first importance that the leaders should set an example of restraint, knowing that what they do will be attempted by others. The conservative tone of Professor Plasse's article will be warmly welcomed in this country.

HOSPITAL PROVISION FOR MIDWIFERY

The important article on fever in the puerperium, which has been already referred to, is worthy of careful study. In discussing contact infection the author emphasizes the risk that, after the birth of the child, attention may be relaxed and errors of technique may consequently occur. It is strongly advised that changes of gowns, gloves, masks, and dressings should be made before the genital canal is examined for lacerations, for that is the moment at which the risk of infection is greatest.

Another interesting point brought out in the same article is the effect of the great increase of hospital accommodation for midwifery which has occurred in the U.S.A. during the last ten years. In ten of the largest cities from 56 per cent. to 85 per cent. of the total births now occur in hospital, and yet "the increased hospitalization has not decreased, but has rather increased, the total morbidity and mortality" (p. 328). This unexpected result is attributed in part to the impossibility of providing the hospitals with the highly trained personnel, both medical and nursing, which they require to deal with the larger number of cases, and, further, it has not been sufficiently recognized that the "parturient woman must be separated from the sick and from all sources of possible contact infection." It would appear that provision is lacking, in the extensions, for the isolation of suspect and infected cases—a defect which is by no means peculiar to the U.S.A. The fact is that in the campaign against maternal mortality the primary requirement is, not more hospital beds, but better trained doctors and midwives.

It is impossible to notice them in detail, but other articles well worthy of attention are those on breech presentation and on abortion in relation to maternal welfare.

France

[FROM OUR CORRESPONDENT IN PARIS]

Reminiscences of Calmette and Roux

Professor Konrad Birkhaug, of the Pasteur Institute in Paris, has recently drawn attention to a curious episode in Calmette's life, and to some of Roux' most characteristic ways. Calmette, it will be remembered, remained at the Pasteur Institute in Lille while it was occupied by the Germans, who accused him of sending wireless messages to French headquarters. His laboratory was searched for wireless apparatus, and nearly stripped of scientific instruments. He was accused of using his experimental pigeons as messengers, and when several pigeons were found with the legs ringed and marked with a serial number and the name "Antwerpen," the situation became dramatic. Calmette declared that these pigeons were used for the transmission of fowl tuberculosis. His explanation was not believed, and he was asked to

show the laboratory records of his experiments. Under a threatening guard he searched through his files, and the meticulous order with which he kept his records doubtless saved his life. He not only found the required data, but also the bill of purchase signed by his assistant. It proved that the pigeons had been sent him from Antwerp, and that their serial numbers corresponded with those stated in the bill of purchase. The incident was not, however, closed. A post-mortem examination was ordered by the commanding medical officer, and was performed by the German bacteriologist Pfeiffer. The one pigeon examined proved to be tuberculous, and the accusation against Calmette was withdrawn. "Fate played me a kindly trick that time," he remarked afterwards, "for among all the pigeons inoculated with tuberculous material, only the one examined had contracted tuberculosis."

As for Roux, Professor Birkhaug says that if one had come across him in the gardens or the corridors of the Pasteur Institute, without knowing him, one would have instinctively asked: "Who is this queer old man?" Here he wandered to and fro on his daily rounds, old, grey, and poorly clad, stooping, sallow, and pathetic; he conveyed the impression that being alive was to him a source of grief. But within this pitiable outward frame was a highly critical and richly endowed personality. He refused to accept the salary to which he was entitled as Director of the Institute. "I really don't need the money," he would say, "and they give me board, room, light, and heat, and whenever I become hungry the maid brings me food. The Pasteur Institute needs the money more than I." When called out on professional duties in inclement weather he would turn up the collar of his overcoat as he hastened to catch the nearest bus or tram. He would not use a taxi: "A taxi costs too much, and we need the money for scientific work." His extreme modesty and frugality knew no limits, and science and hard work were for him the two most important things in life.

Doctors Murdered by the Insane

It has recently been calculated that every year some three to seven French doctors are murdered by their patients. The annual mortality is between 0.10 and 0.25 per thousand. Little wonder, therefore, that most life and accident insurance policies discount this special risk to which the medical profession is subject. It would seem from certain expressions of opinion that much could be done to protect alienists and others who are most likely to be injured by the insane. As Dr. G. d'Heuqueville points out in a recent number of *La Presse Médicale*, a goodly proportion of these murders are committed by persons with a long record of previous acts of violence. To illustrate his point he quotes the recent case of a woman who tried to murder a provincial professor of neurology. During the great war she was repeatedly dismissed for acts of insubordination when an army nurse. She became the mistress of a doctor, and was known to have brandished a revolver in his face. Later she married a doctor, by whom she had a child, and over the child's dead body she wove a persecution mania. She was confined in an asylum, but succeeded in escaping. She promptly brought an action against her husband and discharged a revolver in the law court, wounding him. She gained access to the consulting room of the medical superintendent of an asylum, at whom she fired five revolver shots. In Paris such patients are already being dealt with more strictly and systematically than heretofore. Those who have been discharged from asylums are liable, on the first exhibition of eccentricity, to be promptly conducted to the special police infirmary, where they are examined by psychiatrists with powers to inter-

them or set them free. There is also Dr. Toulouse: at the Henri-Rousselle Hospital he has organized a system of prophylaxis, one activity of which is the dispatch of specialists to the homes of persons denounced by their neighbours as mentally abnormal. These visiting specialists may, if need be, sign admission orders, on which action is taken forthwith. For well-to-do mental suspects an investigation, by a commission, has been proposed, on which psychiatrists, magistrates, and legal experts would be represented.

The Care of Cardiac Cases

In a recent communication to the French Academy of Medicine there was an account of the organization Dr. Vaquez has provided for patients suffering from heart disease. Aided by generous American friends he founded in 1929 the association "Aide aux Cardiaques." This association begins its work in the schools, where, with the help of the teachers and school inspectors, the subjects of heart disease are picked out and kept under special supervision. When they leave school, occupations least likely to injure them are chosen. One of the most effective means for assuring continuity of supervision is the child's health passport, on which his physical ailments are recorded. As the child passes from school and runs the gauntlet of examinations for industrial employment or military service, the record of such a passport is invaluable to him. The "Aide aux Cardiaques" follows its protégés through adult life, intervening with advice, material aid, and consultations with employers when a breakdown threatens or actually occurs. Young as it is this association has already been the model on which similar organizations in Rumania, Czechoslovakia, Spain, Mexico, and the Argentine have been, or are being, founded.

The Sick Stranger Within the Gates

The French are more than a little embarrassed by their many resident visitors. The healthy swell the ranks of the unemployed, and the unhealthy occupy hospital beds to which the French taxpayer must subscribe. There is also the special problem of the foreign lunatic injudicious in his choice of targets. In 1925 there were 19,500 admissions of foreigners to the public hospitals in Paris; this was 7 per cent. of all the hospital admissions. By 1930 this figure had grown to 33,485, and the percentage to 12. In 1931 there was a reduction to 28,563 admissions (11.5 per cent.), but even so the figures are impressive. The ratio of sick foreigners to the total varies from 4.8 to 6.2 per cent. In 1913 there were 10,125 mental cases admitted to the asylums of the Department of the Seine. By 1931 this figure had increased to 15,815. How many of these are foreigners? Statistics available for 1926 show that among 14,257 lunatics admitted to asylums in the above area in that year there were as many as 560 foreigners, or 3.9 per cent. These are minimum figures; they do not take into account the sick foreigner who dispenses with the hospitality of public institutions in Paris.

"What's in a Name?"

Much, to judge by a recent legal verdict in France. The case shows in what an uncomfortably invidious position the tradesman may find himself when he tries to express admiration for a pioneer of medicine by tacking his name on to a proprietary remedy. An enterprising dentist, having devised a presumably new formula for a tooth paste, permitted a company to exploit it. The company called itself "Laboratoires Pasteur et Compagnie," and the paste it sold was called "Dentifrice Pasteur." The authorities of the Pasteur Institute refused to accept this new product as a complimentary

gesture, and were the more inclined to take exception to it as some of the new company's correspondence wandered by mistake into the Institute. Accordingly, a formal protest was made in the autumn of 1931. In response to this the company introduced the letters "A & B" between the words "Laboratoires" and "Pasteur"; at the same time omitting the termination "et Compagnie." This shuffling, in the opinion of the Pasteur Institute, made confusion worse confounded, for now the public might be beguiled into believing that the letters "A & B" stood for two of the many laboratories within the Institute. In the interests of the public and the good name of the Pasteur Institute it was deemed necessary to bring an action against the pseudo-Pasteurians, who have just lost their case, and who have been condemned, among other things, to publish the findings of the Court in five newspapers to be selected by the Pasteur Institute.

Scotland

Royal Infirmary, Edinburgh

At the annual general meeting of the Court of Contributors to the Royal Infirmary of Edinburgh Sir Thomas B. Whitson, who presided, said that the annual report was one of the most important that the institution had issued. During the past year 20,159 patients had been treated in the Infirmary, of whom over 60 per cent. had been discharged cured; there had been 14,500 surgical cases. Of the patients admitted 9,252 came from Edinburgh and over 10,000 from outside the city. There had been 69,000 out-patients, an increase of 3,000 on the figures for the previous year. The question of motor accident cases was causing serious concern; 428 persons injured in such accidents had been admitted to the wards, while 437 had been treated as out-patients, and it was calculated that the treatment of these cases had cost the institution £3,593, while the amount received from insurance companies under the Road Traffic Act had been only £1,504. The average daily number of persons on the waiting list during the year had been over 3,000, and although every effort had been made to reduce the number, the popularity of the institution had prevented the managers from effecting any material reduction. There had been a deficit on the ordinary account of £30,287, with a further deficit of £2,834 on the convalescent house and of £6,693 on Bechmount. The total deficit for the year had been £47,300; this had been covered by legacies and donations to the extent of £40,000, so that the real cash deficit was about £7,000, and this sum had to be taken out of the capital account. There had, however, been bequests for special purposes amounting to over £16,000. Speaking as an accountant, Sir Thomas continued, he did not like to use legacies as ordinary revenue, for the main reason that, as a result of the long-continued high taxation, the amount to be received from legacies in the future was bound to fall. The Infirmary had a limited public to which it could appeal for subscriptions, since all the other cities of Scotland had their own local hospitals to support, and, although appeals were constantly made to Scotland from hospitals in England and the south, it would serve no good purpose to make any appeal either to London or to the rest of England. In Edinburgh at the present time there were only 1,340 individuals or firms who subscribed £1 and upwards. There were, he estimated, 10,000 people in Edinburgh who lived in houses of a rental of £50 and upwards, and if the municipality, contrary to the public wishes, should be forced to take over the Infirmary, the assessment on a rental of £50 for hospital

purposes would much exceed 20s. The total ordinary expenditure for the past year had been £148,000, but the managers had been paying very particular attention to expenditure, and this was £9,000 less than in the preceding year. It was to be regretted that the original proposals for the extension had had to be seriously curtailed. It had been found impossible to erect a combined gynaecological and maternity hospital and a nurses' home, and the scheme had had to be restricted to a maternity hospital and a new nurses' home. Even the cost of this was likely to exceed the funds at present raised for the purpose by £100,000. Meanwhile the appeal was in abeyance as the time was unsuitable, but it would be renewed at a later date. The annual report for the year from October 1st, 1932, to September 30th, 1933, showed that the ordinary income had been maintained at the same level as for the previous year. The average cost per occupied bed had been £152 as against £160 in 1931-2, while the average cost per patient per day had been 8s. 4d. as against 8s. 9d. The scheme for building a new pavilion to house the skin department and the venereal diseases department had made considerable progress, and it was anticipated that the work of construction would be begun early in the present year.

Diet in Health and Disease

In a recent address to the Women Citizens' Association, Edinburgh, Dr. Chalmers Watson surveyed the knowledge gained in recent years concerning the pre-eminent importance of diet in the prevention and treatment of disease. In medicine of the future, he said, successful management would be largely in proportion to the attention paid by the medical practitioner and the public to diet, to the psychological factor, and to the study of what was comprised in the term "the healing powers of nature." Increasing attention was being directed to certain deficiencies in ordinary diets, which were regarded as the fundamental cause of many common ailments, and which arose from the devitalizing of food by modern methods of preparation and preservation. For many years highly skilled laboratory workers had sought to determine the nature of the illusive substance or property called "vitamin," and to manufacture vitamin preparations which could be added to food or administered in medicinal form. The general experience of practising members of the profession, however, had indicated that the clinical value of such vitamins fell far short of expectations based on laboratory teaching. The impression was steadily gaining ground that the best way of administering vitamins was to give fresh foods of suitably mixed and varied kinds, especially fresh vegetables and fruits. The addition of any vitamin to the diet was unnecessary if adequate attention was paid to the value of good fresh milk, good butter, wheat grain which had not been debased by the process of manufacture, fresh fruits, and vegetables. Authorities had come to regard with misgiving the existing tendency to add medicinal vitamins to foods.

Scottish Housing Association

Presiding at the annual conference of the Scottish Housing Association in Glasgow Mr. Joseph Sullivan said that when the Royal Commission on Housing issued its report it was stated that 237,000 houses were required in Scotland to raise the level of housing, and to reduce the number of one-apartment dwellings, while 10,000 were required annually to meet the ordinary wastage. Mr. Joseph Westwood, former Under-Secretary of State for Scotland, said that no material progress had been made since 1919 in dealing with Scottish housing problems. The greater part of the responsibility for this should be laid at the doors of the local authorities. The census of 1931 had revealed that in the county of Lanark 12.6 per

cent. of the population were living more than four to a room, while in other districts conditions were not much better with 10.4 per cent. in West Lothian, 8.1 in Renfrew, 6.6 in Stirlingshire, and 7.5 in Glasgow. There were also over 3,000 two-roomed houses in Scotland where there were more than nine persons to a house. The minimum standard should be a three-apartment dwelling. At the present time too many people had to consider a suitable rent rather than a suitable house. The total cost to the State of dealing with housing in Scotland since 1919 had been £14,818,882. He believed that, if suitably tackled, the housing problem in Scotland could be solved by 1936.

Public Assistance Attendance in Fife

A scheme for medical attendance on public assistant patients was considered at a meeting of the Public Health Committee of Fife County Council at Cupar on January 4th. Dr. G. Pratt Yule, county medical officer of health, said that the cost of the Public Assistance Department in Fife had increased by £17,000 during the last year, and the cost of the able-bodied poor alone had increased by £15,000 in the past two years. There were anomalies in regard to medical attendance; one parish medical officer received a salary of £28 for five patients, another £50 for twenty-six patients, while in the more industrial part of the county a medical officer with 1,050 patients received only £125, and another with 1,211 patients £160. Increased poverty in West Fife had thrown burdens on the medical practitioners altogether out of keeping with the payments made to them. The object of the scheme now advanced was the distribution of the work throughout the profession. It was proposed that the "open choice" method should be adopted, and that the rate of payment should be fixed at 3d. per week for a family, and 9d. per month for the individual. The estimated cost of the new system was £1,788 as against the present salaries of medical officers of £1,838. It was believed that this scheme would be equitable to all practitioners, and would be agreeable to the poor, who would have more say in the choice of their doctor. A sub-committee was appointed to investigate the scheme, and to give consideration to attendance upon the unemployed who had now ceased to be entitled to medical benefit under the National Health Insurance Acts.

England and Wales

International Exhibition of Cripples' Work

The third international exhibition of cripples' work will be held in the Colston Hall, Bristol, next October under the auspices of the Central Council for the Care of Cripples. The previous exhibitions were in Exeter in 1929, and in Nottingham in 1931. The principal objectives are to stimulate and encourage the work of cripples and to assist their education by an interchange of ideas and methods. The organization of this year's exhibition is being undertaken by the Winford Orthopaedic Hospital, the Bristol Crippled Children's Society, the Frenchay Park Sanatorium, and the Rotary Club of Bristol. It is proposed to charge a rent for the stalls, ranging from £2 according to size, the smallest being 8 ft. by 4 ft. The following categories will be included: handicrafts taught in hospital schools; occupational corrective work under the surgeon's orders; home work by bed-ridden or seriously disabled cripples; the work of those training for employment in the open market; the work of employees in undertakings established on a commercial basis for the disposal of skilled work done by crippled persons; and the work of inde-

pendent craftsmen. The exhibition will not be run for profit, and all fees will go towards the expenses of running it; any surplus will be allocated by the organizers at their discretion. It is hoped that every exhibitor reserving a complete stand will send a representative to take charge of it, but where this is not possible the exhibition committee will make arrangements for the charge of stands locally. Special efforts will be made to attract commercial and other buyers likely to be interested in the wares. Great success attended the two previous exhibitions, and it is hoped that the forthcoming one will prove even more popular in view of the marked advances which have been made since then in the education of cripples. Applications for stalls and notice of intention to participate in the exhibition must be sent by May 1st, 1934, to the honorary organizing secretary, Mrs. Hey Groves, 25, Victoria Square, Clifton, Bristol 8, who will welcome suggestions for improving the arrangements. A number of trophies and challenge cups will be open for competition.

National Institute for the Deaf

According to the annual report for 1932-3, the National Institute for the Deaf has quite outgrown its present premises in Bloomsbury. A library is required for persons who come to consult the literature on deafness; a room is needed for a lip-reading centre; meetings of the committee and of allied bodies are poorly accommodated, and the provision for the staff is quite inadequate. A fund is being opened, therefore, to enable the Institute to remove to more suitable premises, possibly in the west central part of London. Gifts have already been received to this end. It is suggested that conferences might well be held in various localities to enable the community to realize the immense amount of unrelieved suffering that awaits attention. The future possibility is envisaged of an Act whereby county and county borough councils would be empowered to deal with the deaf on lines similar to those for the blind. The recommendation of the late Dr. Eichholz for the constitution by the Ministers of Health and Education jointly of a standing advisory committee would have more far-reaching beneficial effects than could be expected to accrue from any other proposal made hitherto. The report contains numerous illustrations of the various activities carried on by the Institute in spite of its present handicaps. The accounts for the year showed a balance of £700 income over expenditure, due to an increase in the amount received from donations and legacies mainly, and not to the more permanent source represented by subscriptions. Yet if the Institute is to obtain its much-needed expansion of premises and activities there will have to be a larger annual income. It is pointed out that, whatever degree of State assistance may be reasonably hoped for in the future, the nature of the work among the deaf is such as to demand a continuance and increase of personal individual support. The prevalence of irregular practitioners who claim falsely to be able to alleviate deafness is again lamented.

Remuneration of Medical Staff at London Mental Hospitals

Following upon representations made by the British Medical Association that the scale of pay for assistant medical officers is less favourable than that prescribed in the Askwith memorandum, the Mental Hospitals Committee of the London County Council has reviewed the current rates of pay for medical staff in institutions under its management. The Askwith memorandum proposed for assistant medical officers at mental hospitals a minimum commencing salary of £350, rising by four annual increments of £25 to £450, with emoluments of board, lodging, and washing, and an additional allowance

of £50 a year to the possessor of a diploma in psychological medicine. The scale adopted by the London County Council for assistant medical officers in the mental hospital service does not provide for residential emoluments, but furnishes an inclusive money payment which, at the minimum of the scale, is £475 a year, and, after deduction of £117 in respect of charges for full board, lodging, and washing, leaves a net cash remuneration of £357. This is more than the Askwith minimum, but the Council's scale provides for only three increments, the first of which is not payable until the D.P.M. has been obtained. After careful consideration it is now proposed that the present scale of remuneration shall be amended to provide for an increment of £25 at the end of each of the first four years' service, but the initial scale rate is to be reduced to £470, instead of being £475. The allowance of £50 a year to the holder of the diploma will still obtain. Each of the four increments, however, is to be conditional upon the submission of a certificate by the medical superintendent, to the effect not only that the conduct, work, and general efficiency of the officer are in all respects satisfactory, but that if he is not in possession of the diploma, he is making proper endeavours to secure it, and also that he exhibits qualities which, so far as can be seen, point to his being suitable at a later date for promotion to a post of divisional responsibility. A condition that the appointment shall be determined at the end of three years if within that time the officer has not obtained the diploma is to be continued, and strengthened by a proviso that retention in service after three years shall depend on the submission of a definite report by the medical superintendent that the officer has shown himself to be entirely suitable for promotion if and when opportunity arises. With regard to existing staff, it is proposed that officers on the present scale who are in possession of the diploma shall receive a further increment, beyond the maximum of the scale in force since April, 1931, of £20 a year, but subject to the proviso that the total remuneration, including this allowance, shall not exceed £627. It is also proposed that the remuneration of house-physicians appointed to the mental hospital service shall be increased to £365 a year if non-resident. According to the scheme approved in 1931 officers of this grade were to have a salary of £230, without emoluments, but so far no appointment of house-physician has been made to the mental hospital service, probably because the rate of pay has not been sufficiently attractive.

Medical Officers in Slum Clearance Schemes

Additional medical staff will be required in the public health department of the London County Council in connexion with the carrying out of the Council's accelerated programme of slum clearance. At present the work on the medical side relating to housing is performed by a divisional medical officer, and it is believed that two more whole-time medical officers will be required. It is also the view of the Council that to obtain suitable candidates some prospect of permanent appointment should be offered, and that in view of the responsible duties to be carried out those appointed should rank as divisional medical officers (scale of salary £800, rising by increments of £50 to £1,000). On the completion of their work in connexion with the slum clearance scheme, which it is anticipated will be in sight to ten years' time, they will be allotted to other branches of work in the department. The medical officer who will be in control of their work, and will have additional responsibilities, is to be given temporary rank as principal assistant medical officer (£950-£50-£1,250). From the onset of the slum clearance scheme additional work will be created, including the preparation and giving of evidence at local inquiries,

and the examination and report upon proposals of metropolitan borough councils for dealing with areas within their boroughs.

Guy's Hospital Founder's Day

Founder's Day at Guy's Hospital was commemorated on January 6th by a special service in the hospital chapel and the reopening, by Dr. Luke Paget, formerly Bishop of Chester, of the crypt, where lie the remains of Thomas Guy. For eighteen months past work has been proceeding in the crypt, the discovery having been made that the foundations of the chapel were by no means secure. Supports have now been carried down fifteen feet below the springing level of the vaults, and the chapel stands as firmly as when it was built 200 years ago. At the same time the vaulting and walls of the crypt have been cleaned of the whitewash with which they have been covered for about 150 years, revealing the fine old brick-work beneath, and a mosaic floor has been laid down between the tombs of Thomas Guy and three famous surgeons of the hospital who were buried there near the founder—Astley Cooper, William Hunt, and John Love.

CORRESPONDENCE

Team Work

SIR,—The annotation headed "Team Work in Medical Practice" which appeared in the *Journal* of January 6th calls well-timed attention to the inspiring address on the influence of medicine on surgery delivered to the Hunterian Society by its president, Mr. W. E. Tanner. The address, charged with home truths, acknowledged those responsible for recent advances in medical science, but at the same time revealed between the lines the uncharted drift of medicine and surgery in many directions. It is suggested that the complexity of modern medicine has led to a dangerous increase in the number of specialists. Specialization is regarded by Mr. Tanner as dangerous in the hands of those who have not had sufficient experience in the science and art of medicine and surgery as a whole. "The true surgeon must not be content to be a mere craftsman; he may laugh at the stethoscope, but he should use it, for he has no right to say he knows nothing about the chest." He adds, "The medically minded surgeon is a great asset, for it is from him we may expect real advance and achievement." With similar thoughts Dr. Charles Mayo declared that we were getting to know more and more about less and less.

Mr. Tanner may have struck a note out of harmony with a fashionable refrain, but it calls us to attention, it makes us think. Without suggesting for a moment that the specialist has only the little knowledge which is dangerous, it would be admitted by the specialists themselves that their viewpoint is limited and circumscribed. It will be conceded by all that this circumscribed knowledge is deep and convincing. It plays an important part in remedying a particular defect in a small portion of a complex machine. The difficulty arises when we consider how often one defect is dependent on other more remote defects, and how the machine often must be overhauled as a whole before the fault can be isolated.

With specialization, as it exists to-day, we cannot, for example, expect the genito-urinary surgeon to be an authority on the intricate and all-important lesions of the cardiovascular system which afflict his patients in considerable numbers. It is unreasonable to request an orthopaedic surgeon to undertake treatment while obscure diseases of the central nervous system or disordered metabolism cloud the issue. The gynaecologist, consulted by the obese woman, whom he has attended in the past during pregnancy, may be confused as to whether the

presence of gall-stones contributes to the symptoms in a case of pelvic disorder. The surgeon who confines himself exclusively to the abdomen is conscious of the fact that mistakes could be eliminated if he had a wider outlook, and frequently is in need of further advice. The cardiologist may have doubts about the state of the thyroid gland or the presence of infection in the biliary tract.

It is clear that the complexity of modern medicine to which Mr. Tanner alludes demands one of two alternatives. If the patient belongs to that large group (from which emergency and traumatic surgery is excluded) requiring careful investigation, either a number of specialists must be summoned to the bedside, which is often impracticable, or the consultant in the first instance must have a wide experience of surgery or medicine as a whole. The need for a specialist may come later. The necessity for a consultation is decided in the first instance by the general practitioner. All will agree with Mr. Tanner that it is upon the general practitioner that the successful handling of any patient, whatever the disease, depends.

In selecting the consultant a difficulty arises. The physician in view may have too academic a mind to be of service in a clinical problem, the suggested surgeon may be "the mere craftsman" who is quite ineffectual in a consultative capacity. If the case is *prima facie* a surgical one the general practitioner is not always in a position to realize that, whereas the combination of good surgery and good craftsmanship is ideal, the latter divorced from the former is a menace. It is a complex problem for those outside the ranks of surgery, but it deserves careful attention. The fundamental distinction which may exist between good surgery and good operating may indeed be only fully appreciated by those who lean towards surgery, and who have gained experience by travel abroad. (Preconceived ideas may be shattered by travel, but out of this wakening good may come. The shaking of a disposition to self-assertion and dogmatism may prove the first step towards a distinguished career.)

It is possible in a few sentences to outline the attributes of a good surgeon and to draw a distinction between him and "the mere craftsman" to which Mr. Tanner alludes. In the one case many hours are spent at the bedside in personal conclave with medical and laboratory colleagues. Quality and not quantity is the goal. "Safety first" are the watchwords. Days or weeks may be occupied in pre-operative preparation and in refreshing the memory from current literature. No stone is left unturned to secure in advance a minute knowledge of what Lord Moynihan referred to as the "pathology of the living." The right moment is chosen for operation; the procedure is carried out with mature judgement and meticulous care. The post-operative period, often pregnant with sinister possibilities, is personally supervised. In the fatal case the post-mortem is attended by the surgeon, together with all those colleagues who shared the responsibility of diagnosis and treatment.

On the other side of the picture may be seen the handyman, content with operative dexterity, and with the favourable impression left upon ill-informed observers. In this case the ward work has been neglected, and information, when sought from the physician, radiologist, and other co-workers, has been accepted second-hand. Pre-operative and post-operative care in the modern sense have been disregarded. Surgery practised thus does not result in the less than 1 per cent. mortality in such conditions as Graves's disease, at best the morbidity is high.

Team work in surgery goes further than that to which Mr. Tanner had time to refer. It is futile to attempt major surgical procedures in the belief that modern standards can be reached with ever-changing assistants and anaesthetists, with unfamiliar equipment, and in a varying surgical environment. Without uniformity in

these respects men of ability and promise are condemned to a position of mediocrity as judged by the surgical world of to-day. Young recruits who visit famous clinics abroad come home impressed. They have witnessed departments presided over by an all-powerful chief, with his permanent or semi-permanent first and second assistants, reinforced by highly trained subordinates. Facilities for investigation and research are at his hand and his command. The daily work proceeds under the same roof both for pay patients and for the reverse. Time and efficiency are thus conserved. Members of the team, nurses included, by long association can almost anticipate the thoughts of one another. Those who in commencing their career are less fortunately placed, in one of the uncultivated fields of surgery at home, may seek reform, but the dice are too heavily loaded against them, and they become submerged by a combination of bolstered traditions and insular habits. The economic question comes in, but the fact remains that it is in the large and rich centres that mediaeval workmanship prevails and flourishes. The best team work often is practised in smaller places where poverty prevails.

The influence of medicine on surgery, and of team work upon both, can be best appreciated by those who travel. The mortality and end-results in different centres throughout the world should be studied and compared, and finally an effort should be made to imitate that system which gives the best service to a trusting but ill-informed public. The moment appears ripe for thoughts of reform in many institutions, both time-worn and new, for the scrapping of antiquated conceptions, and for a radical change.—I am, etc.,

London, W.I., Jan. 7th.

W. I. DE C. WHEELER.

Continuous Intravenous Saline

SIR,—As one of the first, if not the first, to use intravenous saline infusion, in massive or repeated doses, for the treatment of haemorrhage, I am much interested in the method of continuous use advocated by Messrs. Bailey and Carnow. (My first case occurred on April 24th, 1888, see *Lancet*, i, 1892, pp. 1289, 1357.) But I wonder whether, at least in the case of haemorrhage, it would not be equally efficacious and more convenient if given *subcutaneously*, after the volume of the blood had been restored by the intravenous method.

With regard to their suggestion that "an enterprising firm of druggists should put up in ampoules" the saline, I may say that the late Mr. Martindale, more than forty years ago, made for me glass tubes containing 2 drachms of sodic chloride in solution, and sealed during ebullition. They were exhibited at the December meeting (1893) of the Obstetrical Society of London (*Transactions*, vol. xxxv).—I am, etc.,

London, W., Jan. 6th.

HERBERT R. SPENCER.

SIR,—I should like to support what Mr. Hamilton Bailey and Mr. Carnow say in their article on this subject in the *Journal* of January 6th. I have used the method intermittently for several years. During the last two years I have employed it as a routine procedure both before and after operation in certain dehydrated cases, and reported my opinion in my Hunterian Lecture, which was published in the *Lancet* on June 3rd and 10th, 1933.

Anyone who has employed this method often enough to compare its effects with those seen after the use of the more usual procedures cannot fail to have appreciated its greater value, which is largely dependent, I think, on these factors—namely, the fluid is delivered into the blood stream with certainty, in known quantities, and slowly; the rate can be varied according to requirements. I usually give it at the speed of one drop per second, and have administered as much as forty pints without

having to move the cannula to another vein. I utilize one of the veins at the elbow as a rule, and do not find it necessary to restrict the arm movements beyond warning the patient to keep the limb reasonably still; it is, of course, a different matter in the case of a restless patient. Mr. Bailey and Mr. Carnow say it is unnecessary to be concerned about the temperature of the fluid. I am not sure about this. Anyway, it is perfectly simple to run the tube through a small radiant-heat appliance, and this is my practice.

This method of intravenous administration permits the addition to the circulation not only of fluid but of other substances, and presently, with the help of biochemistry, I have no doubt we shall be able to make use of it as an artificial gland, which will temporarily deliver to the circulation in a reasonably physiological manner such elements as may, for the time being, be absent or diminished. Indeed, in one or two instances it has already been so employed.—I am, etc.,

Leeds, Jan. 6th.

E. R. FLINT.

SIR,—I was much interested in Mr. Hamilton Bailey's description of a method of continuous intravenous use of saline, gum arabic, etc., but I am sorry that he attributes its origin entirely to the United States, as I can assure him that it was in use in Bristol in 1926, under a similar technique.

Two points about his method (and ours), however, I have never been able to make my mind up about. (1) At what pressure (that is, at what height should the funnel holding the saline be) should the injection be given? The number of drops depends on the size of the cannula. (2) What is the total maximum that can be administered in, say, twenty-four hours safely?

One case I remember—a case of amputation in Raynaud's disease—developed oedema of the lungs after twenty-four hours. I am in most full agreement with Mr. Hamilton Bailey in the choice of a small vein, as this ensures slow percolation, though we had only a small well-paraffined cannula available. This is a line of treatment which I have always felt has a very large field of usefulness, not only in surgical but also in medical cases, especially those in which the continuous administration of a drug not well tolerated hypodermically is needed. I instance acute streptococcal septicaemia, and the need for an intravenous antiseptic.

Incidentally, I have noticed in a case of septicaemia treated with mercurochrome intravenously (not continuously) marked pink tinging of urine, faeces, and sweat, as in Mr. Hamilton Bailey's case.—I am, etc.,

Bath, Jan. 6th.

WARREN MORRIS.

Marking X-Ray Films

SIR,—In the *Journal* of December 16th, 1933 (p. 1133), Mr. H. A. T. Fairbank made an appeal for the marking of x-ray films with the patient's name and the date of the examination. This practice is universal in the case of private patients sent to radiologists in London and, I think, elsewhere; but, as Mr. Fairbank has pointed out, it only too frequently happens that the patient, regardless of any question of means, is sent to the nearest cottage hospital for a radiographic examination.

All round London to-day is a ring of such hospitals. In almost every one there is an x-ray outfit, put in at the instance of the sellers of apparatus, who start their campaign by telling the hospital secretary that an x-ray outfit will pay for their hospital. The result is that each of these small institutions is equipped to do x-ray work, and films are taken, on which some unfortunate radiologist is supposed to report, in the hope that wealthier patients will be referred to him at his consulting rooms. But, as

things work out, the net result is that practically all the patients of the district are referred to the x-ray department of the small hospital, and little or nothing in the way of fees comes through to the radiologist as a consultant.

When Mr. Fairbank or any other consultant is handed unmarked films I would suggest that he should ask the doctor who has brought the case where and how the films have been taken. I think he will find that, as a rule, the films have been "borrowed" from the department of one of these small hospitals, where the radiologist's services have been given for nothing, or for a nominal fee, and the films have been removed before he has even had time to review them and mark them.

The real tragedy of this situation lies in the fact that the more efficiently the radiologist does his work at the hospital the less hope is there that any patient will be sent from that district to consult him in London. No consultant in any branch of medicine has a heavier outlay for equipment, or has to pay a larger rent for the accommodation necessary for his work, than the radiologist. Nevertheless, in my experience, I have never known an instance of films sent out from a hospital department unmarked; but how can the radiologist help it if he comes to the department and finds that the films have been abstracted without his knowledge or consent?—I am, etc.,

London, W 1, Dec 28th, 1933.

J. L.

Painful Injections: An Avoidable Cause

SIR,—The investigation to be described was undertaken as a result of sharp pain experienced by patients who were receiving hypodermic or intradermal injections. Difficulty was encountered at a diphtheria-prevention clinic during the process of Schick-testing, and it was at first suspected that the Schick toxin contained some irritant substance. Some of the toxin was accordingly returned to the Wellcome Physiological Research Laboratories, but, after exhaustive tests, no fault could be found in the material. I then remembered that Dr. V. J. Glover, medical officer of health for Waterloo-with-Seaforth, in his annual report for 1932, made some remarks which might have some bearing on the subject. He had been in the habit of soaking inoculating syringes in methylated spirit, and had traced painful reactions to this source. The nuisance ceased when he boiled his syringes in water instead of washing them out with spirit.

Although I and many of my colleagues had been in the habit of boiling all syringes, yet, in the case of Schick-test injections, the needle of the syringe had been dipped in spirit after each injection. It thus appeared possible that when the syringe was being charged with Schick toxin a small bead of spirit ran down the needle into the toxin bottle. In this manner it will be seen that the last quantity of toxin in the bottle might well contain a percentage of spirit. It was also realized that by dipping needles in spirit between injections drops of the spirit might adhere to the needle and run down to the point as the latter was being introduced into the skin.

Accordingly 1 in 20 dilutions in normal saline were made from the forms of alcohol and methylated spirit ordinarily used for cleaning and mild sterilizing purposes. These selected were: (1) absolute alcohol; (2) industrial methylated spirit (colourless); (3) ordinary coloured methylated spirit; (4) a well known brand of "surgical spirit" having an aromatic odour. Of these dilutions 0.2 c.c.m. was injected into the skin of my forearm, and also into the arm of a medical colleague. A thick control injection of normal saline was given. The results are of interest.

Solutions 1, 2, and 3 produced a prickling pain on injection which lasted for about half a minute in the case

of absolute alcohol. Industrial methylated and ordinary methylated spirit produced much the same effect, but in both cases the sensation was rather more unpleasant than when absolute alcohol was employed, the pain lasting rather longer in the case of the two spirits. The injection of "surgical spirit" gave rise to severe pain, lasting for four or five minutes. Practically all children would cry if subjected to this degree of discomfort. The control injection of 0.2 c.c.m. of normal saline was practically painless, both at the time and afterwards. The syringe from which the latter injection was given had not been in contact with any methylated spirit.

It appears that the washing of syringes or needles with spirit is apt to cause considerable unnecessary discomfort, and that the pain is greatly exaggerated when so-called "surgical spirit" is used. This substance was employed for the dipping of Schick syringe needles on the occasion when the painful injections giving rise to this investigation were noted. It seems desirable, therefore, to boil syringes on every possible occasion. If, owing to force of circumstances, alcohol must be used, I suggest that absolute alcohol or pure industrial methylated spirit be employed. Subsequently every drop of this alcohol should be expelled from the syringe before filling it to make an injection. For a series of injections, as at a Schick clinic, the needle of the test syringe may be immersed in boiling water for a short time after giving each injection. In the case of diabetic patients requiring hypodermic injections daily, pain such as is caused by spirit remaining in the syringe, or on the needle, assumes some degree of importance. Three hundred and sixty-five or more pains a year are worthy of avoidance if possible.

It would be a kindness if practitioners would inform users of insulin of these facts, as it appears possible that the hard subcutaneous nodules which sometimes develop in the region of insulin injections may be the result of methylated spirit irritation.—I am, etc.,

London, S.E.5, December, 1933.

GUY BOUSFIELD, M.D.

The Tuberculosis Problem

SIR,—I notice in the *Journal* that a correspondent complains of some of the leaders and annotations on the subject of tuberculosis you have lately published, so evidently he does not see the need for overhaul of our present methods. The M.O.H. for Cumberland, in his annual report for 1932, states:

"Under existing conditions I regret to say that I see no hope of any substantial improvement in the tuberculosis problem as it exists in this county. During 1932, of the 189 deaths from all sources of tuberculosis, eighty-nine cases, or approximately 50 per cent., did not come to our notice at all until these cases were within three months of death. It is also obvious that a large number of cases come to our notice at a stage which, if not exactly hopeless, is at any rate sufficiently advanced to render the prospect of cure or arrest of the disease unlikely. This does not give sanatorium or any other form of treatment a fair chance."

It is common knowledge that every sanatorium in the country records the fact that so few early cases are received; and thus it is brought out that our present system does not bring to light, and for treatment, cases in the earliest stages of disease in the great majority of instances. With this failure, it is essential that our present methods of diagnosis should be overhauled and the possibility of protecting the public against the average risks of infection examined.

The value of x rays, in assisting us to form a diagnosis, cannot be overlooked. The part that tuberculosis should play in assisting us has never been clearly defined. Most observers agree that a negative tuberculin reaction shows, in the great majority of cases, absence of living germs of tuberculosis in the body, and in the case of children it

is considered to be conclusive evidence. What is needed is evidence as to the real meaning of a positive tuberculin reaction. Does a positive reaction mean that infection has taken place, and that there are living germs of tuberculosis present? Many observers claim that in the case of children, as soon as a positive reaction is obtained, it is easily possible to detubercularize them by treatment, and that such children do not as they grow up ever become tuberculous. If this contention can be confirmed, it is a most important fact, and should be made known. If it is possible to detubercularize children with a positive reaction who have little or no signs of active tuberculous disease, can we easily detubercularize adults who show a positive tuberculous reaction, and who show no signs of active disease?

The problem of the prevention of tuberculosis has not as yet received the amount of attention it should. It is known that children with a positive reaction and definite signs of tuberculosis can often be permanently cured without any treatment beyond taking them away from their present surroundings and placing them under suitable conditions. Unfortunately, this method cannot be adopted in the great majority of cases, so the possibility of being able to protect children who are in contact with known cases of tuberculosis is of the very greatest importance. The late Professor Calmette advocated the use of B.C.G.; other workers claim that they have been able to protect children by various methods of tuberculin treatment, and the workers at the Tasch Laboratory at Basel claim that they can do so with their antituberculin serum.

In place of criticizing the action of the *Journal*, I welcome its attitude, and strongly urge that these problems, which await a solution, should be carefully considered by such a public body as the Royal Institute of Public Health. The methods advocated by Drs. Chown and Medovy, as described in the *Journal* of December 2nd, should be carefully considered. What is needed is an examination into the reasons for the failure of our methods to bring forward for treatment cases in the earliest stages of the disease, or to cure the disease permanently by any present known treatment, or to protect the public against the ordinary average risks of infection.—I am, etc.,

GORDON TIPPETT, M.B.Lond.,
Medical Superintendent, Northcote
upon-Mendip.

Blaegden, Bristol,
Jan. 5th.

Pay Wards for Tuberculous Patients

SIR,—There has recently been a good deal of correspondence in the Press on the subject of "pay wards" in our general hospitals. In view of this I think your readers may be interested to know our experience in connexion with "pay wards" for tuberculous patients.

Bearing in mind the desirability of providing pleasant wards at reasonable prices, we designed our new eighty-four-bed Bernhard Baron Memorial Hospital accordingly; and we have constructed a number of private wards, with wide balconies, facing south, with bathroom and lavatory accommodation separate from the rest of the hospital. These we find are much in demand, at prices ranging from 3½ to 5 guineas a week inclusive. We feel that "extras" might prove a source of worry to patients, whose recovery would thus be retarded; and so we include everything, even x rays and pneumothorax refills, for the weekly fees indicated.

I feel that the knowledge that there is a demand for this accommodation on these terms may perhaps lead to the provision of similar facilities elsewhere.—I am, etc.,

PENDRILL VARRIER-JONES,
Medical Director, Papworth
Village Suburban.

Papworth Hall, Cambridge,
Jan. 5th.

Physiological Precision and Clinical Medicine

SIR,—In his notice of *Starling's Physiology* (*Journal*, January 6th, p. 18) your reviewer wonders what relation the very precise results obtained by the physiologist "bear to the kind of information which is really of value to the investigator of the human body." I believe the relation to be very close. A difference of no more, and sometimes of even considerably less, than 1/1,000 mm. in the average diameter of a patient's red corpuscles distinguishes a macrocytic, or microcytic, anaemia from a normal blood, and a difference of no more than a very few milligrams of calcium per 100 c.cm. of blood affords the only means of diagnosing a parathyroid tumour. The diagnosis of acidaemia and alkalaemia depends upon the discovery of almost infinitesimal differences in the hydrogen-ion concentration of the blood; and indeed the whole subject of clinical biochemistry, which is of such enormous importance in the modern methods of diagnosis, rests upon very minute differences in the quantitative composition of the blood.

The scientific physician visualizes the time when the very exact measurements obtained in the physiological laboratory will enable him to elucidate many more of the clinical problems with which he is daily confronted. Your reviewer quotes as an example of the lack of relationship between physiological precision and clinical application "the exact time relations measured in thousandths of a second of the waves passing over the auricles of the heart." May I point out that an exact knowledge of even such minute time relations can be usefully applied in clinical medicine? The presphygmic or isometric period of a ventricular systole—that is, that period at the beginning of the systole when the ventricle acquires sufficient tension to overcome the diastolic pressure in the aorta (or pulmonary artery) in force open the semilunar valves and drive the blood into the big vessels—is believed to last no more than 0.05 second (the whole systole occupying 0.3 second). Mathematical considerations based upon hydrodynamic principles tell us not only that the duration of this period is prolonged in the case of a leaking auriculo-ventricular valve, but that the amount of lengthening varies logarithmically with the size of the leak. Indeed, it is possible to derive a formula by means of which the exact size of the leak can be calculated from the observed duration of the presphygmic period. But for such an estimate to be made possible it is, of course, necessary to know "the exact time relations measured in thousandths of a second of the waves passing over the auricles of the heart."—I am, etc.,

London, W 1, Jan. 6th.

W. M. FELDMAN.

Ether Convulsions or Heat-stroke?

SIR,—Will you allow me space to suggest that heat-stroke might be an alternative diagnosis to that of ether convulsions in the interesting case described by Mr. A. Dickson Wright in the *British Medical Journal* of December 30th, 1933 (p. 1210)?

The history of the case suggested that the child possibly might have been susceptible to the effects of the sun. During the hot weather the child had been ill for four days and was also constipated. There was considerable toxæmia at the time of operation. It is possible that the heat-regulating mechanism might have been upset by the combination of unaccustomed hot weather, constipation, and the administration of atropine, causing the development of heat-stroke. The clinical description of the attack bears a strong resemblance to a case of heat-stroke.

I venture to offer this explanation for the convulsions because, when I was attached to a hospital in Mesopotamia, it was considered inadvisable to give

atropine to patients before operation in the hot weather on account of its effect in decreasing the heat loss. I neither saw nor heard of any case of ether convulsions during the summer months when conditions were favourable for its occurrence, although ether was largely used as an anaesthetic.

There arise from these remarks two points, which probably have already received consideration: (1) The rectal temperature should be taken as soon as fits develop under ether anaesthesia. (2) Nembutal should be tried in heat-stroke cases suffering from convulsions which are not controlled by the usual methods and after due attention has been given to any malarial complication.—I am, etc.,

London, W.I., Jan. 3rd.

F. W. G. SMITH.

Left-sided Stance for Urethral Instrumentation

SIR,—In the *Journal* of December 30th, 1933 (p. 1211), the senior surgeon of the Kashmir Mission Hospital, under the heading of "Litholapaxy Simplified," writes: "It is customary for the surgeon, when passing catheters and bougies, to stand upon the left side of the patient; when manipulating a lithotrite, however, this position places the surgeon at an obvious mechanical disadvantage. For many years I have adopted a central position." Among the advantages claimed for this and for other technical details are that "turning movements of the beak of the instrument to right or left, and search for fragments in a retroprostatic recess, are greatly facilitated."

While any statement on stone emanating from India necessarily commands attention, one is surprised to hear of a search with the lithotrite for stone fragments in a retroprostatic recess. With sufficient prostatic enlargement to justify the description of retroprostatic recess, one would rather suppose prostatectomy, with incidental removal of the stone, to be the usually indicated line of treatment. With regard to standing on the left of the patient when passing a catheter or bougie, this position is recommended by some authorities, but I have never understood why, or what advantage is to be so gained, unless the operator is left-handed, or ambidextrous, or has specially trained himself to stand on the left. With these exceptions, the consequent mechanical disadvantage, which is obvious in the case of a lithotrite, is still present, if less obvious, in the case of a catheter or bougie. The left-sided position is certainly not customary with those whom I have seen passing catheters and bougies. If any rule be needed, it is to stand where one is most comfortable, and that will nearly always be on the patient's right.—I am, etc.,

London, W.I., Jan. 2nd

ALEX. E. ROCHE, F.R.C.S.

SIR,—I have read with interest Mr. Neve's memorandum in the *Journal* of December 30th, 1933 (p. 1211), and agree that it is difficult to operate from the left side. But the central position as described by him does not appear to provide a comfortable support for the left elbow, which in my opinion is essential.

I stood or sat on the right side and rested my left elbow on the table, which gave a firm support and enabled a long operation to be performed with a minimum of fatigue. For beginners at least litholapaxy would be more simple and less dangerous if textbooks omitted to illustrate the lithotrite beak downwards picking up pieces of stone from the floor of the bladder, as in all cases (except those with enlarged prostate or sacculated bladder in which litholapaxy is contraindicated) fragments of stone can be picked up by depressing the floor of the bladder with the instrument and opening the blades.

When difficulty is experienced due to accumulation of debris, the bladder should be washed out. This is best done by filling the bladder with a syringe, then gently pressing the abdomen above the pubes with the left hand, whilst shaking the cannula with the right. It is not usually necessary to use an evacuator until the end of the operation.—I am, etc.,

Renal Histology and Nephritis

SIR,—I was attracted to Dr. John Gray's paper in the *Journal* of December 23rd, 1933 (p. 1165), by the title, but was disappointed to find an incomplete story. The very great difficulty in determining the mechanism of the kidney function—how the blood volume, the alkalinity of the plasma, the molecular concentration, and the percentage of nitrogenous and other waste products in the blood, and possibly the return to the blood of special products formed by the kidney (an internal secretion related to striated muscle mass and function), are controlled—naturally renders the picture of renal states in disease correspondingly difficult of interpretation. The difficulty is not lessened by leaving aside from consideration an integral part of the kidney—for example, the medulla, which Dr. Gray does not mention.

Since the blood from the vascular arches passes on the one hand into the cortex, and on the other into the medulla, it is clear that the resistance to the blood flow in the medulla must condition the blood flow in the cortex. Since the uriniferous tubules in the cortex dip down into the medulla and loop back from there into the cortex before entering collecting tubules, it is plain that the resistance to the flow of urine through the medulla must influence the transudation of water from the glomeruli into Bowman's capsules. That these factors are of paramount importance is shown by the effect of therapeutic measures in acute nephritis and allied states (anuria). I mention the beneficial effects of limitation of fluids, of venesection, and of other measures to lower the blood pressure—for example, spinal anaesthesia in acute anuria—and decapsulation of the kidney. These can only be supposed to act by relieving a medullary congestion, by which tubules in the part are compressed and even occluded. Examination of the kidney in the early stages of acute nephritis, as in so-called suppression of urine, will, I think, show a marked, a clearly pathological, congestion of the medulla, especially near the intermediate zone. Relief of this condition clinically causes the urine locked in the convoluted tubules of the cortex to escape, so that blood can enter the cortex more freely than before and more urine be formed, provided changes in the cortex (extravasation of blood into the glomerular tufts, etc.) have not occurred to prevent it. The filtration hypothesis—that the pressure of the blood in the glomerular tufts is high, whilst the pressure in Bowman's capsules is low—has always seemed to me impossible. The capillary walls and the investing layer of Bowman's capsule are so thin and delicate that if the pressure of the blood within the capillaries were high whilst the pressure in Bowman's capsules were low (as is commonly supposed) the glomerular tuft would expand, completely filling Bowman's capsule, and effectually block the tiny orifice through which the water escapes into the convoluted tubules. During activity the glomerular tufts never fill the Bowman's capsules: there is always a space (filled with water) surrounding these tufts.

We know quite well that the kidney will only work when the blood pressure is sufficiently high, and we must thus suppose that during distress the pressure of the blood in the glomerular tufts is considerable. The

pressure of the water in Bowman's capsules must also be considerable: it must correspond—being, indeed, only less than the pressure of the blood by the tensile strength, the resistance to expansion caused by the endothelial cells of the capillaries and the thin, similar, tessellated cells of the capsule investing them. To obtain the necessary pressure of the urine in Bowman's capsule, the urine apparently is prevented from escaping too readily by the circuitous route of the uriniferous tubules. I see no other explanation for the existence of Henle's loops in the medulla, and I know of no other put forward by anyone.—I am, etc.,

Rugby, Dec. 23rd, 1933.

Pharyngeal Haemorrhage

SIR.—Dr. P. Shackleton's two cases (*British Medical Journal*, December 23rd, 1933) and Mr. E. D. D. Davis's letter (January 6th, 1934) interest me very much. In the *British Medical Journal* of May 24th, 1919, I reported a case in which, as the only successful means of stopping a dangerous and intractable haemorrhage after tonsillectomy, I was compelled to tie the external carotid in the neck.—I am, etc.,

London, W.1, Jan. 5th.

H. LAWSON WHALE.

Rest in the Treatment of Neuroses

SIR.—While there is no doubt that Dr. J. W. Astley Cooper (December 30th, 1933, p. 1231) is right in calling attention to the importance of rest in the treatment of the neurotic of the anxiety type, he does not mention that a considerable proportion of the neurotics met with in general practice are individuals who simply cannot afford to stop work. The anxiety underlying the symptoms may be related to the work which the patient is doing, but financial obligations have to be met, and the patient has to struggle on.

I should be interested to hear how Dr. Cooper would treat, for example, a man with dyspepsia of emotional origin who would almost certainly lose his job if he were to go sick for a month.—I am, etc.,

Edgbaston, Dec. 31st, 1933.

PHILIP R. KEMP.

Comments in the Coroner's Court

SIR.—Surely all members of the medical profession are amazed at the power possessed by the lay coroner and at the damage that can arise from one of his sweeping conclusions. Severe injustice may be inflicted upon a firm, an individual, or an institution by the condemnation which he can mete out, often, it would appear, without sufficient information. It is merely a further proof of the danger of a little knowledge.

A patient recently was seen at hospital with apparently minor head injuries, detained, and later allowed home; he remained well for a week, then developed coma, had a decompression performed, and died. At post-mortem a small fracture not seen at operation was found; yet the following day the Press, with large headlines, commented on how an institution could have allowed a man with a fractured skull to leave. Every well-qualified man has seen such cases sufficiently often not to blame anyone, but rather to wonder that it does not happen more often.

Again, the value of various narcotic drugs, and their makers, can be put into disrepute through a much too sweeping condemnation. If the number of successfully treated cases were given the fatalities would show an almost negligible proportion, yet a single fatal case—not definitely attributable to the drug—gets so much publicity that harm must result.

Often at an inquest the hospital is represented by a junior house-surgeon, or even one of the nursing staff, and as a result, in many cases, remarks are allowed to go unchallenged and thus may appear in the lay Press. In the possible event of such happening it is surely the duty of the member of the visiting staff involved to put in an appearance at the inquest. Most coroners do not intentionally produce the injury that often occurs; it is often the result of the cross-questioning of a clever barrister with a weak opposition.

The coroner's court should deal merely with the primary facts of the patient's death, let further details go to a higher court, where there will be expert witnesses and advice from both sides; or else do away with the coroner's inquest, and have, as in Scotland, a private court of inquiry.—I am, etc.,

December 27th, 1933

CONSULTING SURGEON

"Bornholm" Disease

SIR.—On reading Dr. Carter's letter in the *Journal* of December 23rd, 1933, I was forcibly reminded of an epidemic which occurred when I was at school at Winchester in the 'eighties. So far as I can remember, the symptoms were identical with those which Dr. Carter describes. I remember being suddenly attacked by the disease when I had obtained special leave to go into the town to do some shopping, and having the greatest difficulty in getting back to my house. Whether any records are kept which would throw light on the subject I do not know. It would be interesting to inquire. At the time we called it "the plague."

May I, as one who has visited Bornholm and admired its beauties and its many objects of antiquarian interest, venture to suggest that it is perhaps not quite kind to attach the name of "Bornholm" to a disease which surely cannot be attributed to any conditions that are peculiar to the island.—I am, etc.,

Hampstead, Jan. 2nd

E. A. H. JAY.

Road Dangers

SIR.—Recent correspondence on this subject in the *British Medical Journal* has rightly stressed the responsibility resting with individual motorists. Another source of road accidents must, however, be kept in mind—that is, the careless pedestrian. In the report on fatal road accidents issued by the Ministry of Transport for the first six months of 1933, it is shown that 3,025 persons were killed on the road, of whom no fewer than 1,581 were pedestrians. These latter fatal consequences would have been avoided, almost entirely, if pedestrians practised a single simple rule—one that has been frequently emphasized, publicly in *Things to be Desired*, renewed in your columns of February 18th last, and individually on many occasions. The rule is—for ordinary two-way traffic—"Always look first to the left and then to the right before stepping off a path or pavement when crossing a road."—I am, etc.,

BURTON HILL, SUMNER, JAN. 1st W. W. SHEPHERD, D.P.H.

SIR.—In reply to Dr. CLAYTON, I certainly agree that safety on the road depends on the "good will" of all. As I would say, "consideration for others" of individual drivers. But, alas! there are a small number of drivers who consider no one but themselves, and these are frequently the cause of accidents, and they should be taken off the road. It is the duty of the "authorities"—that is, magistrates—to see to this. But so often they altogether lack the necessary knowledge of what actually constitutes dangerous or inconsiderate driving that they merely fine these drivers and trust travel will be safer.

almost as severely. At present the inconsiderate driver has no "fear of penalties," for he is likely to be treated much the same as if he had left his car too long outside a shop or his back lamp had gone out without his knowledge.—I am, etc.,

December 30th, 1933.

M.D.

The Beer Campaign: A Medical Protest

SIR,—You will doubtless have seen in the general press of the country a reference to the speech recently made by Sir Edgar Sanders with regard to the projected campaign for advertising beer. Directly on receipt of a copy of his speech we wrote on behalf of this league to a large number of representative men and women in the medical profession, feeling sure that whatever their views may be with regard to the use of alcohol as a beverage, they would certainly deprecate an attempt "to instil the beer-drinking habit into thousands, almost millions, of young men who do not at present know the taste of beer, that they may become the mainstay of the public-house."

We had intended to get a very much larger list of signatures, but the statements made by Mr. Samuel Storey, M.P., the Archbishop of Canterbury, and others, have drawn so much public attention to the matter that we decided not to continue our manifesto any further. I thought that you would like to see the statement and the names of those who so readily and immediately responded to our letter. We received a large number of letters accompanying the signatures which show in a very unmistakable manner the strong feeling that Sir Edgar Sanders's lamentable speech had evoked.—I am, etc.,

COURTENAY C. WEEKS,
Director and Medical Lecturer,
National Temperance League.

33, Bedford Place, W.C.1,
Dec 29th, 1933

* The statement, signed by 261 medical men and women, runs as follows:

"We, the undersigned, view with serious apprehension the projected campaign which would seek to enlist the young men of the country who do not know the taste of beer into the beer-drinking habit. As a result of several causes and tendencies, there has been a vast improvement in national sobriety in recent years. There has also been a corresponding diminution in the disease, poverty, crime, and inefficiency which are traceable to drink. The beverage use of alcohol is not really necessary to the highest exercise of individual and social life. We therefore deprecate the initiation of an effort to promote the beer-drinking habit among the young, and we would regard the success of such a campaign as a step backwards and as detrimental to the best interests of individual and national welfare."

The Services

DEATHS IN THE SERVICES

Lieut.-Colonel John Blacker Whitha Buchanan, R.A.M.C. (ret.) died on November 7th, 1933, aged 70. He was born on August 26th, 1863, and was educated at Trinity College, Dublin where he graduated M.B. in 1884 and B.Ch. in 1885. Entering the Army as surgeon on January 30th, 1886, he became lieutenant-colonel after twenty years' service, and retired on February 4th, 1911, but resumed for service in the war of 1914-18. He served in the South African war in 1899-1901, when he took part in the actions at Colenso, Tugela Heights, Pieters Hill and Laings Nek, and in the relief of Ladysmith, and also in operations in the Transvaal and Orange River Colonies. He was mentioned in dispatches in the *Lancet* on Feb. 1st, 1901, and received the Queen's medal with seven clasps.

Medico-Legal

LEGAL OWNERSHIP OF X-RAY FILMS

From time to time the question is raised of who is the legal owner of an x-ray film or print. An idea of the position from the point of view of the medical man may be gained from a summary of some correspondence which appeared in the medical press last year. For the sake of convenience, the writers will be called A, B, C, and D. Writer A, a general practitioner,¹ sent a patient to a radiologist for examination. The patient subsequently entered a mental hospital on a voluntary footing, and the writer sent the films to the medical superintendent. The patient's relatives claimed the films as their property on the ground that they had paid the fee of the radiologist. The writer suggests as possible alternative owners: (1) the radiologist who sent them to the general practitioner to support his report; (2) the patient or her relatives who paid the fee; (3) the general practitioner, since the films are part of the report addressed in confidence to him; and (4) the medical person for the time being in charge of the case, as temporary owner.

B, a practising radiologist,² considers the practice of giving films to the patient a very unsound one; patients occasionally refuse to settle his fee until the films are handed over; and he then points out to them that the films are his property and that the patients are paying for the skill and knowledge required to obtain and interpret the radiograms.

C, a specialist in bone-and-joint surgery, who uses a diagnostic x-ray outfit in his consulting room, takes the view³ that in many cases the radiogram is one of the means whereby he forms his opinion, just as his inch-tape informs him of measurements. If he chooses to screen the patient instead of exposing a film, the patient cannot claim as his property the fleeting impression on the screen. The taking of the radiogram is not considered in fixing the consultation fee. Similarly, if a surgeon sends a patient to a radiologist the patient is paying for the radiologist's opinion and not for the film, which therefore remains the property of the radiologist. The surgeon who sends the patient is entitled, C thinks, to see the films, and usually finds the radiologist eager to co-operate.

The fourth correspondent, D, quotes⁴ with approval a motion on the status of radiologists passed by the German Röntgen Society in 1912. This contained the claim that all plates, dia-positives, tracings, orthodiagrams, and teleröntgenograms prepared for the diagnosis of the case are the property of the radiologist, just as the histological preparations belong to the consulting pathologist. The röntgenologist will—the motion continues—always be ready as a matter of courtesy to place his plates and prints at the disposal of the consulting physician.

SOME AMERICAN DECISIONS

So much for the medical point of view. As an introduction to the legal point of view it is useful to look at the American decisions. In *Hindley Hospital v. Gage*,⁵ a Michigan hospital sued a former patient for non-payment of part of his account. He had been radiographed in the hospital and the charge had been included in his bill, but he had refused to pay it unless the films were delivered to him. The hospital sued him before a justice, who decided for the patient, so it appealed to the circuit court of the county. At the hearing of the appeal, at which the patient did not appear and was not represented, the court held that patients bought and the hospital sold knowledge and experience, not the material of an x-ray film, which was the property of the hospital. It thought, moreover, that the protection of the hospital against

¹ *Lancet*, 1932, i, 55.

³ *Ibid.*, p. 282.

⁴ *Ibid.*, p. 164.

⁵ *Jour. Amer. Med. Assoc.*, 1931, xcvi, 1512.

litigation might depend largely on the proper preservation of the films.

In *Thocker v. Barnum*,⁴ the circuit court of Ingham County, Michigan, found no evidence that the films in dispute had any intrinsic value, and they could therefore not be recovered by an action of replevin. This point would hardly be material in England, for the action of replevin has been obsolete for many years; it used to be brought by people whose goods had been wrongfully distrained by creditors. On the other hand, the point that the films had no intrinsic value seems sound as expressing the view that the patient pays for service and skill only, and the court touched the real point at issue when it went on to say that where x-ray films and pictures are taken by a physician there is no implied undertaking that they will be handed over to the patient. The court found it to be customary for the physician to retain the films as part of the records.

In the latest case, *Leas v. Otto*,⁵ a dentist in Ohio took a radiogram of a lady's teeth, for which he charged her husband ten dollars. At a second visit he stated his diagnosis and gave his advice on the work to be done, and charged for this service five dollars. The husband decided not to have the work done and asked for the film, which the dentist declined to give up. The husband thereupon paid the five dollars for the advice but refused to pay the ten dollars for the taking of the film, so the dentist sued him for this sum. The only question at issue was the ownership of the film.

The court gave judgement for the dentist on the doubtful ground that an x-ray film is not a chattel in the sense that it can be bought or sold. Nevertheless, the rest of the judgement shows that the judge appreciated the essentials of the situation. He found that a film has no value for anyone but the doctor or dentist with sufficient knowledge and skill to diagnose the particular case; it is part of his equipment and of the information on which he diagnoses the case and prescribes treatment. The interpretation, he said, is the all-important part of an x-ray examination, and the film is simply the basis of the interpretation. The practitioner sells, not material, but knowledge and experience. He buys apparatus and the material for making radiograms, and when a radiogram is made it becomes part of the records of the particular case. It is customary for the practitioner taking a film to keep it, for it is just as necessary that he should keep a film as that he should keep a temperature chart or any other record. Moreover, he relies largely on it for his protection (presumably against litigation, which seems to be a far more serious affliction to the medical profession in America than it is here). In the face of this custom the law will not infer an implied agreement to transfer the ownership of a film from doctor to patient when no such agreement has been expressly made; in the present case no such agreement was expressed.

With respect, the learned judge was perhaps a little incautious in laying down so sweeping a rule of law as that an x-ray film is not a chattel in the sense that it can be bought or sold. A film is just as much a chattel as anything else; he himself implies that its ownership can be transferred by express agreement. He would have been better advised to avoid this dangerous word altogether, as the issue does not in the least concern the law of property, but is purely one of the exact nature of the contract to be implied between doctor and patient.

STUDIO PHOTOGRAPHS

It is perhaps worth while to take a glance at the legal relation between a professional photographer and his subject. This relationship has not much in common with that which exists between a radiologist and his patient, but is the nearest analogy to it and may throw a little light on the problem. It is first of all necessary to put firmly on one side all ideas concerning copyright, for they are irrelevant to the question of who owns a photographic negative. Copyright merely enables its possessor to

prevent the legal owner of the negative from using it in certain ways—chiefly from selling reproductions of it. The ordinary contract between a photographer and his customer, like most contracts, is not fully expressed, and when a dispute arises the court has to infer from the circumstances what the exact conditions of the agreement were. It is settled law that in the ordinary way, when a customer has his photograph taken, and there is no express agreement to the contrary, the customer pays for a certain number of prints and the negative remains the property of the photographer. If the customer wants to buy the negative and the photographer to sell it they must make an express agreement; if they do not the court will not imply one, for this is not a usual condition of such contracts. This agreement need not be in writing, but if one of the parties wishes to enforce it against the denial of the other he must bring adequate evidence that it was made.

Another implied condition which the courts will infer unless there is an express agreement to the contrary is that a photographer who takes a photograph of a customer to supply him with copies must not, without his consent, print copies from the negative for sale or exhibition. To sell or exhibit copies of the negative is therefore a breach of his contract. The photographer owns the negative, but what the law will let him do with it is another matter.

In *Pollard v. Photographic Co.* (1888) Mr. Justice North thought that the bargain included an agreement that the prints were to be appropriated to the use of the customer only. The glass negative was the property of the photographer, but the man was using it for an unlawful purpose, which amounted to a breach of his agreement, in exhibiting copies therefrom in his window. No one suggested that the photographer had wronged the sitter because the negative was the sitter's property which had been used in an unauthorized fashion; the wrong was in the breach of a confidence which he had tacitly agreed to respect.

THE INTENTION OF THE PARTIES

When a court of law has to interpret a doubtful contract, one of the most important problems before it is to discover what the parties meant their bargain to include when they made it. When a patient goes to a medical man for x-ray examination, the contract is not only unwritten but also largely unspoken. The general practitioner may have told the patient what the fee will be and arranged an hour for the examination; otherwise the conditions are all "implied," which means in this instance that no one has bothered much to consider what they are. If, therefore, a patient ever goes to an English court claiming the delivery-up of radiograms, or is sued for the radiologist's fee and says in defence that he has not received the films, the court will have to decide what contract the parties really intended to make. In making this decision it will first inquire into the usual custom in the profession, since if the parties have not expressed an intention and the transaction seems to be a usual one they will generally be thought to have intended to follow the current custom in their dealings with one another. The court will therefore inquire: Is it the custom of the profession to hand over the x-ray films to the patient as part of the service for which he pays? If the court found that such a custom did not exist it would be very slow to suppose that the parties intended, at the time they made their bargain, to do something unusual. It would only infer an unusual condition from evidence that the parties had expressly agreed to it—evidence either of an actual agreement in so many words or of some behaviour by one or both parties which clearly showed that they had agreed to this condition. Moreover, if the patient declares that he and the radiologist agreed that he was to have the films he must prove it; and if he declares that it is the custom for films to be handed to the patient, he must prove that before he can win his case. It is not for the radiologist to prove the contrary, though, of course, he would be well advised to bring evidence that it is customary for radiologists to retain

⁴ *Ames Legal Report*, 1902, XXXII, 697.

⁵ *Journal Amer. Med. Assoc.*, 1932, C, 137.

films. As far as legal ownership is concerned, the court would probably find that it remained with the radiologist or other medical man who took the films. As there seems to be no doubt that this is really the custom of the profession, it could not seem at all likely that any party could succeed in establishing a claim to the films taken in the ordinary course of medical practice.

THE PATIENT'S POINT OF VIEW

Nevertheless, the patient also has a point of view, which has not been stressed by the medical men who have discussed this subject and has not been reflected in the American judgements. An ordinary photographer owns the negative, but the customer has rights over it which restrict his ownership. Similarly, a surgeon or radiologist probably owns the x-ray film, but a patient may have rights to which that ownership is subject. Suppose, for instance, that a patient breaks the head of a femur and consults his family doctor, who calls in a London surgeon, who supervises treatment and, when the patient is able to move about again, sends him to a radiologist for examination and report. Several years later the patient is living in Manchester and fractures the bone again at the same site. He consults a Manchester surgeon, who wishes, in order better to understand the injury, to see the films of the original fracture. Can the patient, as of right, demand that the films be sent to the Manchester surgeon?

By the standards of justice which are recognized in ordinary life, irrespective of legal views, the patient certainly seems to have a right in these circumstances to benefit by the information which the films contain. He has paid for a service which includes the preparation of a permanent record of the state of his case at a certain time. If in the future his medical adviser needs the information for the better treatment of his case, surely the original fee which the patient paid the radiologist includes the future use of the films—irrespective of who owns them—at any time when they might be of use. Many medical men, and possibly many radiologists, will agree with the principle that the part a radiologist plays in the case is not a momentary one, but continues as long as the data revealed by his examination are relevant. Again, if the patient, soon after being examined by the radiologist, changes his surgical or medical adviser, he is surely justified in expecting the radiologist to give his new doctor full information about his case and to show him the films, if not without further fee, then at least for a minor one commensurate with the slight trouble of preparing and sending a duplicate report.

In practice, as C says, radiologists are nearly always eager to co-operate for the good of the patient; they are no less helpful and generous than other specialists; and the question of whether or not the patient has a legal right to the use of the films in such circumstances as these does not often arise. As it has never been settled by an English court its answer remains a matter of pure opinion, unsupported by any solid legal foundation. It would be possible to engage in lengthy and possibly quite interesting speculation and argument on which way the court would be likely to decide each of a series of hypothetical cases based on a variety of circumstances, but it would be quite profitless. In the writer's opinion, however good a right the patient may have by the standards of ordinary men, he would almost certainly not succeed in enforcing that right in a court of law.

ITS LEGAL VALIDITY

Suppose a patient has paid for an x-ray examination of his knee some years previously, and now wants the radiologist to lend the films or prints to another doctor, and the radiologist refuses. Has the radiologist broken an implied term of his contract? The court would ask what the parties had intended by their bargain when they made it. Will the patient stand in the box and swear that he understood one of the implied terms to be that if his knee gave trouble years afterwards, the films, or prints from them, were to be available to his medical man? It is most unlikely that such a contingency ever crossed his mind. The radiologist, for his part, could quite truth-

fully deny that he had ever agreed, or intended, to part unconditionally with any films he might make in the course of examining this patient. On the evidence the court could hardly assume that the parties had respectively claimed and admitted in their contract the right which has just been mentioned. When courts interpret contracts they do not inquire closely into the "rights" of the parties by standards of natural or legal justice. They are concerned with the bargain the parties have actually made, and if it is a one-sided bargain that is the business of the parties, not of the court. The court will often suppose that the parties meant to follow the current custom. If the patient could show that it is customary for radiologists to put their films at the patient's disposal in the circumstances described, he might successfully maintain that the radiologist had broken an implied agreement to follow that custom. But because many radiologists give a certain facility as a matter of professional courtesy, it by no means follows that they are obeying a professional custom, and there is very little likelihood that the patient would succeed in proving that it was the custom of radiologists to give this facility. Suppose, to take the matter to its extreme, the court found that the radiologist actually had broken his contract. Could the patient get specific performance of the implied agreement to send a report and the films to the new medical adviser? The films would be of very doubtful value without the report, and the report of an unwilling specialist on a case five years old would be of even less. Moreover, the radiologist might have lost the films, and they are irreplaceable. As the court never gives specific performance where it cannot enforce it effectively, this remedy would not be available. The only other remedy is damages. What damage has the patient suffered because, owing to the radiologist's breach of contract, his medical man cannot see the films? It would be practically impossible to prove he had suffered any. He might ask for that portion of the fee which the court considered to represent the value of the service which the radiologist has refused to render. He might ask for the expenses of a fresh radiological examination. All these remedies are heavily tinged with absurdity, and the only conclusion to which it is reasonable to come is that there has really been no breach of contract at all. Even if the patient has a right by ordinary standards to the benefit of the films, it is not one which he could hope to enforce by an action for breach of contract. If the radiologist had lost the films, could the patient get damages against him for negligence? Only if he could prove that the radiologist owed him the duty of keeping them, and it is difficult to imagine what evidence he could usefully bring for this purpose.

The only other case in which the question would be likely to arise is where a radiologist sues for payment of his bill and the patient refuses to pay because the radiologist will not show the films to the new medical adviser. Here again the patient could only succeed if he could show that to lend films was part of the service for which he had paid.

As far as it is possible to form an opinion from the scanty available data, therefore, the patient not only does not own films taken by a medical radiologist, but he would probably find it impossible to make good even a right to the use of them after the radiologist has given his first report.

If this view be correct, correspondent A was right in refusing to give the films to the relatives of his patient. He has respected the moral or extra-legal right of the patient to have the benefit of the information contained in them, for he has put them at the disposal of the medical adviser for the time being.

OTHER SUGGESTED OWNERS

This writer suggested as an alternative owner the general practitioner, since the films are part of the consultational report made to him by the radiologist. It is fairly certain in law that, whoever can claim films made by radiologists, the general practitioner cannot, for the reason that he is not one of the parties to the contract. The agreement with the radiologist is not between the

radiologist and the general practitioner; it is between the radiologist and the patient, the general practitioner acting at all times as the patient's agent and never as a principal. To a general practitioner claiming ownership of a film the lawyer would answer: "What have you paid for it?"—or, in legal terms, "What valuable consideration have you given for it?" The answer is that the general practitioner has given the specialist nothing in exchange for the film and therefore cannot claim to own it. If he argues that his introduction of the patient is valuable consideration, the lawyer will reply that he is no more entitled to expect in return an x-ray film than a portion of the patient's fee; his part is throughout one of agent and nothing else. It is also difficult to see how, as suggested by writer C, he can claim of his own right even to see the films. He is not a party to the agreement and he cannot claim anything. (Of course, if he is not shown the films he may well send his next patient to another radiologist!) Nevertheless, as the patient's agent, it is his duty to uphold the patient's right to have the films shown to his medical adviser. It is also possible that, if the radiologist sends the films attached to his report without reservation, the property in them passes to the general practitioner.

The suggestion that the films are the temporary property of the medical person in charge of the case does not appear well grounded, for in law there is no such thing as temporary ownership; a person who lawfully possesses the property of another has no ownership, though he may have the rights and duties of a "bailee" or a trustee. It is, of course, open to any person, as C suggests, to go to a village chemist who owns an x-ray tube—or, much better, to a properly qualified radiographer—and have films taken of any part of his person. The contract is then obviously for a radiogram or a series of radiograms, but both parties will probably understand the terms beyond risk of dispute.

The British Institute of Radiology has apparently not expressed a definite opinion on the question of who owns films. The British Medical Association, according to writer B, has stated that films taken in hospital belong to the hospital and should be kept there and treated as confidential documents. This view agrees with that of the judge in the Michigan court, and almost certainly with the law of this country. A patient who pays nothing obviously has no claim to a hospital radiogram. A patient who pays a weekly sum obviously pays for board, maintenance, and service, and perhaps pays for skilled treatment and nursing, but can no more claim to be paying for radiograms than for temperature charts.

A patient in a nursing home which possesses an x-ray installation of its own may be in a slightly different position. In many of these institutions the patient is charged specially for such services as the use of the operating theatre, hydrotherapy, or massage, and sometimes a diagnostic x-ray examination is a special item. In this instance he pays a fee for the use of the apparatus and the help it gives in diagnosis. Although the films are part of the apparatus and do not become his property unless there is an express agreement that they should, it seems probable that, having paid for the special service, he could claim the use of them if at a later date a medical adviser wished to see them. He is, it is suggested, in the same position as though he had paid a radiologist's fee as a private patient.

When a general practitioner or a consultant is the owner of a radiographic apparatus and takes films in the course of his examination, the question of ownership or of the patient's right to the future use of the films must hardly arise if, like C, he does not consider the taking of the films in fixing the fee. He is then, it seems, using his apparatus as one means to assist his diagnosis, and both the ownership and the disposal of the films must remain entirely in his hands. Many practitioners who own an x-ray apparatus, however, make their use of it a separate item in the account, and when they do this they seem to place themselves in exactly the position of a radiologist, so that all that has been said about the rights and duties of a radiologist applies equally to them.

CONCLUSION

To sum up, the question of who owns an x-ray film depends for its answer on the intentions of the parties to the contract. When the contract is between a patient and a medical practitioner, the parties will probably be taken, in the absence of an express agreement to the contrary, to have intended to follow the custom of the profession. It is almost certainly the custom that the films remain the property of the medical man who takes them, or under whose direction they are taken. Although many radiologists recognize an informal right in the patient to have the films lent to a practitioner who may at a future time have charge of his case for his guidance in its treatment, it is unlikely that the patient could enforce such a right at law.

Obituary

T. SWALE VINCENT, M.D., D.Sc., LL.D.

Formerly Professor of Physiology, University of London

We had to announce with regret last week the death, on December 31st, 1933, at the age of 65, of Thomas Swale Vincent, M.D. Lond., D.Sc. Ed., LL.D. Manitoba, F.R.S. Ed., F.R.S. Can., latterly professor of physiology, University of London, at the Middlesex Hospital Medical School, and chairman of the St. Albans Division of the British Medical Association in 1932-3.

Swale Vincent was born on May 24th, 1868, the son of J. Vincent and Margaret Swale, and was sent to King Edward VI Grammar School, Birmingham. Proceeding to the Mason University College (now the University of Birmingham), he qualified in medicine at the age of 24, and, finding that his interests lay rather in research than in practice, he studied under Kossel at Heidelberg, whence he returned to Birmingham to take up his first appointment as demonstrator of physiology.

In 1896 his first paper, entitled "The Suprarenal Capsules in the Lower Vertebrates," was published in the *Proceedings of the Birmingham Natural History and Philosophical Society*. The study of the recently discovered functions of the endocrine organs which he thus embraced was destined to be one to which he devoted the greater part of his life, and it was natural that he should welcome contact with E. A. Schafer, the original discoverer of those functions. Soon afterwards the opportunity came in the form of an appointment as British Medical Association Research Scholar, and he went to Professor Schafer's laboratory at University College, where he continued his investigations. He there confirmed his important discovery that in Elasmobranch fishes the interrenal body corresponds to the mammalian suprarenal cortex, while the paired segmental suprarenal bodies correspond to the medulla. In 1897 he succeeded Benjamin Moore as Sharpey scholar, an appointment which at that time carried with it the post of chief assistant in the physiology department, and in 1899 he continued as Sharpey scholar and assistant professor under Professor Starling. In 1900 he was appointed lecturer in physiology at Cardiff. One of his students there was T. Lewis, now Sir Thomas Lewis, with whom he published two papers on the biochemistry of muscle. Sir Thomas Lewis writes to me: "I first knew Vincent when he came as demonstrator of physiology at Cardiff, and soon knew him intimately. He was a vigorous and stimulating personality. It was while working in his class of physiological chemistry that Vincent asked me if I would care to undertake a research with him on the proteins of vertebrate muscle. The request came as a complete surprise to me. I readily agreed, and afterwards worked at his suggestion, and under his supervision, at the harem length of time. I have always been grateful to Vincent for giving me my first introduction to scientific work." He left this post

in 1902 to hold the Francis Mason Research Fellowship for investigating the physiology and pathology of the thymus and other ductless glands, for which purpose he rejoined Professor Schafer in the physiology department of Edinburgh University, which had now become an active centre of endocrinological investigations. He collaborated there with two advanced students—W. Cramer, now of the Imperial Cancer Research Fund Laboratories, and thenceforth his close friend, and W. A. Jolly, now professor of physiology at Capetown.

In 1904 he was appointed to the chair of physiology in the University of Manitoba. He served as a member of the Industrial Fatigue Committee of Canada, and was honorary secretary of the Winnipeg Scientific Club for fifteen years. He had to create the new department at Winnipeg, and when in 1920 he left Winnipeg to return to London as professor of physiology at the Middlesex Hospital, the University of Manitoba paid him a well-deserved tribute by conferring upon him an honorary LL.D. In London it again fell to his lot to reorganize a department of physiology, and its active scientific state when he retired in 1930, to be succeeded by his pupil and former assistant, Samson Wright; bears witness to the success of his efforts. Swale Vincent held many examinations, and took considerable interest in the affairs of the British Association, being secretary of its Ductless Glands Committee since 1898.

Professor Vincent's numerous publications cover a large part of endocrinology. Beginning with a study of the suprarenal glands, he proceeded to investigations on the pituitary, the thymus, the thyroid and parathyroid glands, and the islets of Langerhans. Dr. W. Cramer writes: "He was a prominent representative of the Sharpey-Schafer school of physiology, which, regarding the cell as a basic unit of physiological functions, combines histological studies with experimental technique. The present generation of physiologists, who can buy most of the various internal secretions in a more or less pure state at a chemist's shop, must find it difficult to realize the laborious investigations required to understand the morphological and functional relationships of the different parts of the endocrine organs, most of which are formed as a result of the joining up of histogenetically and functionally different tissues." Swale Vincent laid stress on the existence in all tissues of substances producing a marked lowering of blood pressure, and differing from choline. The subsequent discovery of the important physiological properties of histamine and acetylcholine has shown how potent such substances may be.

Vincent was a careful worker, with a highly critical and sceptical mind—qualities which not only enabled him to make positive contributions of lasting value, but also led him to, at all events, attempt the apparently impossible task of ridding endocrinology of much that smacked of deliberate or unconscious quackery. In this attempt he was courageous and outspoken. He had a high international reputation, and contributed a series of reviews on the ductless glands for the *Ergebnisse der Physiologie*. His opinions were later published as a book, *Internal Secretion and the Ductless Glands*, first appearing in 1912, which soon became a standard treatise, and passed through three editions. He also published, in 1924, an *Introduction to the Study of Secretion*, and in 1929, with Professor Samson Wright, *Introduction to Practical Mammalian Physiology*. Professor Swale Vincent was (as he quoted Dr. Cramer) "a man of firm principles and high ideals on which he would not compromise." He was essentially a shy man, and this sometimes gave an impression of haughtiness, while to those who had the privilege of knowing him well he was a staunch friend and a charming companion. He had a deep love and a great understanding of music, and was himself no mean pianist.

He was president of the Men's Musical Club of Winnipeg. In 1914 he married Beatrice, daughter of Mr. W. Overton of London, who survives him, and had two daughters. To these our deepest sympathy goes.

C. LOVATT EVANS.

ROBERT PROSSER WHITE, M.D.

Consulting Dermatologist, Royal Albert Edward Infirmary, Wigan

By the death of Dr. R. Prosser White, Wigan has lost one of her most distinguished sons and the medical profession an outstanding personality. The only son of the late Dr. James White, J.P., who practised long in Wigan, Robert Prosser was born in 1855, and was educated at the Royal Grammar School, Clitheroe, Edinburgh University, and University College, London, taking the degrees of M.B., C.M.Ed. in 1878, the M.R.C.S. diploma in 1880, and proceeding M.D. in 1890. In 1885 he was elected honorary physician to the Wigan Infirmary, and later became a life vice-president. He founded the skin department, and gave the first x-ray and Finsen light apparatus to the hospital. On retiring from the active staff ten years ago he was elected honorary consulting dermatologist. For many years, up to the time of his death, he was certifying factory surgeon for this area, a post which gave him full scope for the study of his pet subject—occupational diseases of the skin—in which he gained an international reputation as an authority.

Dr. Prosser White was a past-president of the London Dermatological Society, of the Manchester Medical Society, and of the Certifying Factory Surgeons' Association, and a member of the Permanent Committee for the Study of Occupational Diseases constituted under the auspices of the League of Nations at Geneva. He was also Associate Editor of the *Journal of Industrial Hygiene*. Outstanding among his contributions to medical literature is the book on *Occupational Affections of the Skin*, published in 1915, the fourth edition of which is actually in the press. This work has been translated into every European language, and there have been several American editions. A book full of his own work, it is considered the greatest compilation of facts and references that has ever been published on the subject, and will long remain the standard textbook. In 1930 the Labour Bureau of the United States Government invited Dr. White to deliver a series of lectures on the occupational diseases of the skin, but he felt that the strain on his heart would be too great. Dr. White founded an annual lecture in dermatology, to be delivered by an eminent authority selected each year by the council of the Dermatological Society. His articles on naphthalene, dinitrobenzol, and aniline poisoning, baker's itch, and fur eruptions reveal painstaking work, the conscientious mind, and careful judgement. Only those who knew "Prosser," as he was affectionately welcomed by his friends, realized the amount of work embodied in every article he wrote. His knowledge was wide in the fields both of medicine and of men. With his unbounded energy (although suffering from a cardiac disability for forty years) and his keenness in medicine, it is not surprising that he had no time for the uninterested or the slacker.

"Prosser's" love of that branch of medicine which he chose for his life's work was almost equalled by his love for his native town and its people. About the year 1860 he published a manual for the Church Lads' Brigade Medical Staff Corps, and became principal medical officer and surgeon colonel of the Brigade, and Editor of the *Brigade's Medical Corps Manual*. The proper training of the youth was an essential in his view of life, and he took pains to see that it was done. He was much interested in the Wigan Mining and Technical College, and founded a "French travelling scholarship," whereby

Wigan students could spend three months in France, or in any Continental country, to study their special branch. In his younger days the idea of the preservation of records of Wigan led him to commission young artists to paint and make drawings of the old buildings in the town. These are collected in the Public Library. The fifty-fifth picture was added only two years ago. He was also a poet, and several of his poems have been published. His artistic temperament was demonstrated by his interest in music, and this also took a practical and beneficial form; he founded the Wigan Parish Church Musical Fund for the purposes of ensuring an annual organ recital by some well-known organist. In 1924 he founded the Medical Book Trust Fund at the Wigan Public Library. The object of the fund was to buy books on original research in medicine, expensive textbooks, and works in the ancillary sciences. This has been a very valuable and much appreciated branch of the library.

A philosopher, Prosser White's outlook on life is exemplified by his book-plate—a scantily clad man turning away from the lamp of knowledge, the flame of which is a large note of interrogation, and going into the unknown towards the rising sun: the legend is "Why and wherefore." He was a very fine character. Although breezy and cheerful, and going out of his way to help the under-dog, his mind was always on the ultimate good that might accrue from his work. To his widow and sons we extend sympathy in their great loss. "I dare, Prosser."

W. E. COOKE.

JAMES COSSAR EWART, M.D., LL.D., F.R.S.

The death took place on December 31st, 1933, at his residence, Craigfield, Penicuik, of Emeritus Professor Cossar Ewart, who from the year 1882 to 1927 held the post of professor of natural history in the University of Edinburgh.

Born at Penicuik, near Edinburgh, in 1851, James Cossar Ewart took his medical course at Edinburgh University, where he graduated M.B., C.M. in 1874. He never practised, but after a year as demonstrator of anatomy at Edinburgh he was appointed conservator of the Zoological and Anatomical Museum in University College, London. Here he added a considerable number of preparations to the Museum, and engaged in the study of bacteria, collecting the results of his researches in a thesis for the degree of M.D., for which he was awarded a gold medal in 1878, the same year as Koch published his great memoir upon the organisms responsible for surgical infection. In this year also Ewart was appointed professor of natural history in the University of Aberdeen, where in 1879 he established a small marine laboratory. In 1882 he was appointed a member of the Fishery Board for Scotland. He carried out a number of important researches on the fishing industry of Scotland, which were published in such papers as *The Fertilization of Herring Ova* (1884), *Fish Culture in America* (1884), *On Whitebait* (1886), *On the Preservation of Fish* (1887), etc. At the same time he was doing anatomical work, and published *The Locomotor System of Echinodermata* (1881), *The Olfactory Organs of the Skate* (1888), *The Cerebral Nerves of Elasmobranchs* (1889), *The Development of the Limbs of the Horse* (1894), etc.

In 1882 he was transferred to the chair of natural history in the University of Edinburgh, which he held for forty-five years. He was elected a Fellow of the Royal Society in 1893, and received the honorary degree of LL.D. from Edinburgh University in 1928. One of his best-known works, *The Practical Experiments*, published in 1889, dealt with an extensive series of breeding experiments in rats and horses, in connection with which the theory of heredity was investigated. He devoted a considerable amount of attention to the tanning of domestic

sheep and to the development of wool, visiting Australia in 1923. As a result of his work the Board of Agriculture formed in Edinburgh a committee on animal breeding in 1913, and after the war this committee reported the scheme of work of the animal breeding research department in the University of Edinburgh, which, under Professor Crew, was constituted a chair of animal production. Professor Ewart was a pioneer in the application of biology to animal breeding and in bringing a scientific outlook into practical agriculture. He had a large farm at Fairbairns, Penicuik, where he kept a flock of sheep for experimental purposes, and he was made a member of the council of the Woolen and Worsted Research Association at Leeds. He is survived by his widow, a daughter, and a son, who is a surgeon in London.

DR. ALEXANDER PAINE

Dr. F. J. POYNOR writes:

It is with a certain sadness that I noted in the obituary of my old collaborator and friend Dr. A. Paine no allusion to his experimental work on rheumatism. That work revolutionized for this country the study of organic heart disease, arthritis, chorea, and appendicitis. No small achievement. The proofs are to be seen in the Hunterian Museum, and in the schools of the medical faculties of Harvard, Toronto, and Melbourne Universities. I thank God that I have been allowed to have long enough to have done my friend a last honour in the medical Press. Future generations can then at their leisure assess what Paine did for English medicine, and his work will not be forgotten while his collaborator is not only alive, but actually in active hospital service. Countries other than England have much respect for Dr. Paine, and possibly a greater knowledge of his work. The great war and other difficulties broke his health. He was always a reserved man, with that curious temperament, so often a part of genius—for in his work he was a genius—which led him to cut himself adrift from London and all connected with it. He subsequently married, and leaves a widow and one son.

DR. JOHN STEWART

We are indebted to Sir ST. CLAIR THOMSON for the following tribute to Dr. John Stewart of Halifax, Nova Scotia:

The small band of Lister's immediate disciples is rapidly disappearing. We had lately to deplore the death of Hamilton Russell of Melbourne, one of the later of Lister's house-surgeons, who had carried the example of modern surgery to Australasia. Now comes news of the death of a pupil who was one of the most devoted of the apostles of the great master in North America and who, from the depth of his affection, was able to record for both continents some of the most sincere pen-pictures of his beloved teacher. Dr. John Stewart had also the advantage of being one of the small band who, having accompanied Lister from Edinburgh to London, was with him at the most critical period of the *Stoma and Drain* which followed that migration.

This was in 1887. Lister, when accepting the invitation to occupy the chair of clinical surgery in King's College Hospital, stipulated that he should be allowed to bring with him, as assistant, the man who had already been trained in his methods. The late Sir W. Watson-Chalmers came as his house-surgeon and John Stewart as his clerk. They were, each in his way, typical operators of two races which are found in Scotland north of the Grampians. Watson-Chalmers with his reddish hair, coloured beard showed the Scottish strain even in the inhabitants of Stirling, just as his Highland wife suggested his Viking ancestry. Stewart was a tall specimen of the English and Scottish blood, with straight, hardy, dignified, grave, and earthy features, and a soft, clear speech. He had been founded a member of the many learned societies. His list of publications mentions that what he called *Chloroform* (the anaesthetic) arrived at Kew was the result of his own experiments, and the successful use of ether in England was the

at the hospital! But this, he at once adds, was the only embarrassment he felt, for his fellow residents were most generous in welcoming and making smooth the arrival of these Scotch invaders. What he did feel deeply, with astonishment and a naturally loyal resentment, was what he described as the "colossal apathy," the "monstrous inertia to the force of new ideas," with which the evangel of Listerism was received in London. After the excitement of the first novelty had worn off, the Edinburgh invaders were, so far as their message of healing was concerned, left severely alone. The surgeons of the metropolis did not even trouble to come to King's to listen to the expounding of the principles of antiseptic surgery and study the technique founded on them. Students neglected the Listerian wards, as they were not taught the tips to get them through "the College and Hall" (that is, the College of Surgeons and Apothecaries' Hall, the two usual diplomas of those days). After the crowded class of some three to four hundred students who flocked to his clinical lectures, I felt this neglect in London as "a

John Stewart succeeded Cheyne as house-surgeon to Lister's wards in 1878. I was then a first-year student, and naturally, as such, had but a slight and distant acquaintance with him. But I remember the courtly kindness with which he dressed (in a cloud of carbolic spray) my hands, which had been wounded when I got a toss over the handle-bars while riding a high, iron-rimmed bicycle of the "penny-farthing" type. It was many years before we met again. It must have been in 1916 or 1917, when, on going into a Canadian hospital at Havre, I unexpectedly recognized in command the same handsome Highlander, though the black beard had become silvery. He remained in France until the end of the war. From that time we had frequent communications, and it was a delight to see him at the Annual Meeting of the British Medical Association in Edinburgh in 1927, and, although for the last time, at Winnipeg in 1930.

It is interesting to anyone to read Stewart's reminiscences of his great master. It was always an encouragement to note how this devoted and affectionate pupil had been strengthened and guided in his lifework by the inspiration which can be imbibed from a great teacher. What he had learned, in Edinburgh and in London, he freely and gladly passed on to others. Canada is fortunate in having had such a worthy son to illustrate, by his life and writings, the influence exerted by one of the great masters on a devoted pupil.

PROFESSOR IRVING CAMERON

Professor GREY TURNER writes:

No notice of the activities of Irving Cameron would be complete without reference to the regularity with which, for many years, he attended the Annual Meetings of the British Medical Association. I always expected to meet him at this annual event, and he was usually to be found in the Surgical Section. I remember so well that it was he who set the ball rolling in that Section at the splendid meeting held in Toronto in 1906. But apart from the meetings of the Association, he was so proud of his Scottish descent that he made it a practice to visit the tomb of his ancestors each year in order that he might pay his respects to his chieftain, Cameron of Lochiel. His appearance was very characteristic, and his thin, sharply cut features with the goatee beard reminded one of the pictures which used to adorn the pages of Oliver Wendell Holmes's breakfast-table series. In 1930 I called upon him at his own home in Toronto and found him a delightful host. Unfortunately, he was much crippled with some sort of arthritis, and he bitterly regretted that this had prevented him making his customary trip to see his chieftain. But mentally he was as alert as ever, and it was a delight to enjoy his conversation. One of his remarks exhibited that intense loyalty to the Empire which was so characteristic of him. I chanced to mention that I intended to go to Washington, principally because I wanted to take my wife to Mount Vernon, the home of George Washington. His retort was very striking, for he said: "Whatever do you want to go there for? Why, George Washington was a rebel!" He was very

well read and a good classical scholar. Sometimes he spoke at public functions, and while the matter of his speeches was always excellent, his weak voice and rather poor delivery usually ended in his losing the attention of his audience. Irving Cameron was a very lovable man, and I feel sure he will be sadly missed by many friends on both sides of the Atlantic.

The death occurred on December 12th, 1933, of Dr. OSWALD DYKES ROBSON of Somercotes House, Alfreton. Dr. Robson was the son of Dr. William Robson of the Indian Civil Service, and was born in India in 1866. When 4 years of age, however, he was sent to Edinburgh, and travelled by sailing ship round the Cape, the Suez Canal not having been constructed. From George Watson's College he proceeded to Edinburgh University, where he graduated M.A. in 1888, and M.B., C.M. in 1892. After a period as house-surgeon at Leicester Royal Infirmary he purchased a practice at Somercotes, and remained in active work until a few weeks prior to his death. Though he never sought public office, and was never in the limelight, Dr. Robson was universally and deservedly popular with all sections of the community, and not least amongst his own professional colleagues. A member of the Chesterfield Division of the British Medical Association, he took no active part in its work, but could always be relied upon for loyal support whenever the need arose.

H. W. P.

Dr. GEOFFREY FREDERICK DIMMOCK, who died at Harrogate on December 24th, 1933, at the age of 38, had received his medical education at the University of Leeds, where he graduated M.B., Ch.B. in 1926. Before this he had had a long career in the Army. During the war he passed through the Royal Military Academy, and was gazetted lieutenant in the Royal Garrison Artillery. A short time before his death he had taken up flying with a view to obtaining a pilot's certificate. He had also graduated B.Sc. in engineering at the University of Durham. Since qualification he had been practising at Harrogate, where his father, Dr. A. F. Dimmock, is also in practice. He was keenly interested in archaeology, and with Mr. S. Barber took part in the excavations at Knaresborough and Aldborough some years ago. He was a member of the British Medical Association.

The death took place on December 31st, 1933, at Tobermory, Mull, after a short illness, of Dr. DONALD MORISON, one of the best-known practitioners in the West of Scotland. He was born in Mull in 1853, and, taking a medical course at Glasgow University, graduated M.B., C.M. there in 1880. He practised at Beeford, Yorkshire, for thirty years, and then in Mull until his retirement four years ago. He had a wide private practice, and acted as medical officer of health for Tobermory. He was deeply interested in all Celtic affairs, and was one of the founders of the Mull Highland Games. He was enthusiastic also for the maintenance of the Gaelic language.

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated.

MD—(Branch I, Medicine) F. E. Camps, *E. H. Capel, W. I. Carl, V. P. de Souza, E. H. Evans, Mary Fraser, H. Halfonny, *C. H. S. Hares, Alison F. Z. Judd, Nellie I. Lankerton, K. S. May, B. G. McRobb, N. S. Plummer, W. M. Priest, M. D. Rawkins, J. H. Rogers, R. Stanford, W. R. Throver, W. J. Tindall, E. R. Williams. (Branch II, Medicine and Surgery) J. D. S. Hew, * Evelyn E. Goult, J. I. Hackett, J. C. Patrick, Elsie E. A. Rolley, Patricia H. S. Shaw. (Branch III, Surgery) C. Burke, E. Grundy, Dorothy M. Howden, Laura H. Macfarlane, Dorothy Makepeace, C. M. Oakley, R. H. Parris, J. A. Seckman. (Branch VI, Tropical Medicine) *D. J. L. Long.

* Awarded a rank of Honorary.

* University Medal.

The Senate has appointed a special committee to report fully on a matter of university policy on the amount and nature of technological study at present carried on in the University, and as to the feasibility of instituting a new Faculty of Applied Science or Technology.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Lectures

The course of lectures for 1934 is arranged as follows: January 15th and 17th, *Probes* or W. E. Le Gros Clark, The evolutionary origin of the primates; January 19th, Mr. L. R. Broster, The adrenopituitary syndrome; January 22nd, Mr. H. C. Edwards, Diverticula of the duodenum and jejunum; January 24th, Mr. H. C. Edwards, Diverticula of the colon and vermiform appendix; January 26th, Mr. Alan Brown, A clinical research on the radium treatment of carcinoma of the cervix uteri; January 29th, Mr. Arnold Sorsby, Retinal atrophy; January 31st, Mr. K. H. Watkins, The bladder function in low spinal injury; February 2nd, Mr. E. G. Muir, Carcinoma of the prostate; February 5th, Mr. A. A. Davis, The peripheral nerve: its anatomy, physiology, pathology, and surgery; February 7th, Mr. J. M. Yelloly, The study of lymphoid tissue; February 9th, Mr. Cecil P. G. Wakeley, The surgery of the spinal gland; February 19th, Mr. Denis Browne, Talipes equinovarus; February 21st, Mr. C. Bowdler Henry, Aberrant third molars and their menace; February 23rd, Sir Thomas Dunhill, Diaphragmatic hernia (non-traumatic). The lecture hour is 5 p.m.

On February 13th, at 4 p.m., Sir Cuthbert Wallace will deliver the Hunterian Oration.

Medical News

The Hunterian Lecture will be delivered before the Hunterian Society of London, at the Mansion House, on Monday, January 15th, at 9 p.m., by Dr. Jacques Forestier of Aix-les-Bains, on "Rheumatoid Arthritis and its Treatment by Gold Salts."

The annual meeting of the Royal Microscopical Society will be held at B.M.A. House, Tavistock Square, W.C.1, on Wednesday, January 17th, at 5.30 p.m., when the presidential address will be delivered by Mr. Conrad Beck, F.R.S., on "Some Recent Advances in Microscopy."

At the meeting of the Royal Sanitary Institute in the Town Hall, Wakefield, on January 18th, at 5 p.m., there will be discussions on town and country planning, to be opened by Mr. Percy Morris, and on the prevention and control of infective diseases, to be opened by Dr. Thomas Gibson. Before the meeting there will be visits to a housing estate, an isolation hospital, a council school, a milk pasteurization depot, and to the pathological laboratory of the West Riding County Council.

A discussion on the aetiology of acute rheumatism and rheuma in relation to social and environmental factors will take place at a joint meeting of the Sections of Epidemiology, State Medicine, and Diseases in Children of the Royal Society of Medicine (1, Wimpole Street, W.) on Friday, January 20th, at 8 p.m. The speakers will be Dr. J. Alison Glover and Dr. W. S. C. Copeman, and Dr. Reginald Miller and Dr. E. C. Warner.

An address entitled "Traditional Morality and Modern Life" will be given before the British Institute of Philosophy by Professor W. G. de Borch, at University College, Gower Street, W.C., at 8.15 p.m. on Tuesday, January 16th, with Sir Herbert Samuel in the chair. Cards of admission can be obtained from the director of studies, at University Hall, 14, Gordon Square, W.C.1.

A meeting of the Eugenics Society will be held at the Linnean Society's rooms, Burlington House, Piccadilly, W., on Tuesday, January 16th, at 5.15 p.m., when Dr. R. Lancelotti, Dr. E. Mapother, and Dr. C. P. Bicker will speak on "Safeguards in Eugenic Sterilization," with Sir Humphry Rolleston in the chair.

The annual meeting of the International Society of Medical Hydrology is to be held on Sunday, January 28th, to Friday, February 2nd, inclusive, at Zermatt, Valais, Switzerland. The president-elect is Professor O. Vassuth of the Faculty of Medicine of Zurich University. The principal subject for discussion are the thermal bath reaction, the thermal treatment of the diseases, and the therapeutic effects of high mountain climates. There will be taken consideration the climatological and climatological of muds, peats, etc., used in physical medicine. The meeting is open to other medical men

and their wives, at a fee of 20s. and 10s. for the lady. Applications to attend should be made immediately on a form to be obtained from the general secretary, I.S.M.H., 104, Kingsway, W.C.2. A party to the festival, via Dunfermline, is being organized by The Cook and Son, Ltd., and will leave London on January 24th.

The Fellowship of Medicine and Post Graduate Medical Association (1, Wimpole Street, W.) announces that the first of Dr. Clark-Kennedy's lecture-demonstrations at 11, Chandos Street, W., will be on January 16th, at 2.30 p.m., on the subject of radiations; the second, on January 23rd, will deal with nervous dyspepsia. These demonstrations for M.R.C.P. candidates will be given at the same place, as follows: January 16th, at 8 p.m., Dr. Peter Kerley, x-ray films—diseases of the heart and lungs; January 17th, at 4.30 p.m., Dr. Kenneth Harris, electrocardiograms; January 18th, at 4.30 p.m., Dr. Kerley, x-ray films—diseases of the gastro-intestinal tract and bones. Six demonstrations on the interpretation of psychograms will be given by Dr. Mather Conder at 8 p.m. on Tuesdays and Fridays from February 13th to March 2nd.

Designed on lines corresponding to those of the recent winter exhibitions of Flemish, Dutch, Italian, Persian, and French art, the Royal Academy winter exhibition of 1934, which opened on January 6th, gives a comprehensive view of British art from the tenth to the nineteenth century. It consists of paintings in oil and water-colour, drawings, sculpture, engravings, tapestries, furniture, silver and other examples of fine craftsmanship, selected with the purpose of showing that the achievements of British artists, in their characteristic aims and excellences, are worthy of comparison with the creations of other countries.

At a meeting of the court of directors of the Society for Relief of Widows and Orphans of Medical Men, held on January 3rd, with Mr. V. Warren Low, president, in the chair, the death of one of the ex-presidents, Dr. F. G. Crookshank, was reported. Two new members were elected. The sum of £1,998 15s. was voted for the payment of the half-yearly grants to the widows and orphans on the funds. This included £141 5s. as special grants to orphans, to enable them to continue either their education or their professional studies. The widow of a member was voted a yearly grant of 200. The total number of widows at present receiving relief is fifty-three. With the purpose of making the society better known and obtaining new members, a new attractive leaflet has been prepared. Membership is open to any registered medical man who at the time of his election is residing within a twenty-mile radius of Charing Cross. Relief is only granted to the necessitous widows and orphans of deceased members of at least three years' standing. Further information, and application forms for membership, may be obtained from the secretary at 11, Chandos Street, Cavendish Square, W.1.

At a meeting of the General Council of King Edward's Hospital Fund for London, held on January 9th at 10, Old Jewry, E.C., it was reported that the Prince of Wales had appointed Mr. Samuel Stoney, M.P., to be an additional member of the Voluntary Hospitals (Planning) Committee. On the motion of Lord St. Leonards, in the chair, the resolutions provided for the work of the Fund for 1934 were adopted.

The results of two inquiries into diet and health expenditure have just been published. The first comes from the Newcastle Diet Survey and the second from the Economics Research Section of the University of Manchester. From the data obtained it is a surprise to note that, as pointed out in the report of the F.M.A. Nutrition Committee, when one considers the high standards in the purchase of food, the relatively small amount of money actually spent on food, and the fact that the average man spends more on tobacco and the expenses of eating out than on food.

The December issue of the *Manchester and Gt. Northern Medical Journal* contains a paper by Dr. J. H. G. Jones, on the subject of the death of a patient of Professor August Meissner, who died at the age of 77. He had been married for 40 years and for thirty-six years at the time of his death.

The November supplement of the *Bulletin of the Johns Hopkins Hospital* contains a revised student's check list of texts illustrating the history of medicine, compiled by Fielding H. Garrison.

Amongst the latest contributions to King Edward's Hospital Fund for London is the sum of £1,000, being the annual subscription of His Majesty The King, Patron of the Fund.

Dame Janet Campbell, M.D., M.S., retired at the end of 1933 from her post as senior medical officer for maternity and child welfare at the Ministry of Health, and chief woman medical adviser to the Board of Education.

Dr. William Habgood will retire in March, after twenty-six years' service as medical officer of health for the urban district of Sutton and Cheam.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, *British Medical Journal*, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, *British Medical Association House*, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the *British Medical Association* and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:
EDITOR OF THE *BRITISH MEDICAL JOURNAL*, *Aitology*

Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER

(Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, *Medisecta Westcent, London.*

The address of the Irish Office of the *British Medical Association* is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshagh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Chlorophyll and Crème de Menthe

Surgeon Rear-Admiral CHARLES M. BRADSHAW, R.N. (ret.), writes: The late Sir Ray Launester, F.R.S., in an article, "The Simplest Things," in *Science from an Easy Chair* (published 1940), states that chlorophyll "may be seen in solution in the liqueur known as 'crème de menthe,' being used to give it its fine green colour to that preparation." Recently, however, a friend of mine informed me that he examined this liqueur spectroscopically side by side with an ethereal extract of the leaf-green of the nettle, and that whereas the latter showed the characteristic bands in the red of chlorophyll the former did not. Can any of your readers inform me whether the makers of this liqueur have or have not given up chlorophyll as a dye, and, if they have, the nature of the colouring matter now in use?

Convalescent Home

Dr. J. S. McLAREN (Stratford-on-Avon) would be glad to learn of any convalescent home which would take in an elderly gentleman (75 years of age) who is recovering from a nervous breakdown. Not a mental institution, but a home which is not too large, and preferably one with a resident medical officer, and fees about 5 guineas a week.

Mental Allergy?

"A. G." (Bath) writes: Allergy in the physical sphere has, I think, rather a remarkable mental or psychic counterpart. Just as some bodies react violently to usually innocuous substances, so some minds seem unable to tolerate the presence of certain harmless objects. I am alluding to the well-known horror which many people suffer from mice, the well-known terror which many people suffer from cats, spiders, etc. That this fear is an integral part of the mental makeup, and not the result of superimposed experience, seems to be likely from the harmless nature of the creatures objected to. It would be of interest also to know whether the dread is hereditary. It does not appear

to be confined exclusively to the human species, as I have read of a male chimpanzee at the Zoo, of which it was said that "a mouse reduces him to a state of abject terror and makes him scream like a terrified child." This shuddering dislike seems to be usually aroused by living creatures, but I can remember the unspeakable terror with which, during the first few years of my life, I was filled by cobwebs, and when a little older by the sound of a particular steam saw. It would be interesting to know whether these abnormal sensations occur chiefly in allergic individuals or families, as there is so strange a resemblance between the two conditions.

LETTERS, NOTES, ETC.

New Year Honours: Addendum

The name of Major JOHN GILMOIR, M.C., F.R.C.S.Ed., President of the International Quarantine Board, Egypt, upon whom has been conferred the honour of C.M.G., was omitted from the list of New Year Honours published in our issue of January 6th (p. 30).

Treatment of Scabies

Dr. R. R. CLISTEIN (London, E.8), writes: In the *Journal* of January 6th (p. 16) Dr. A. D. Matthews states that he found sulphur ointment and β -naphthol ointment (24-74 per cent.) ineffective in a case of severe scabies. Personally I have found the following ointment valuable in this condition: acid. carbol. liq., mx; sulph. præcip., grains x; resorcin., grains x; paraffin. moll., ad 3i. It invariably relieves itching, and I have never yet observed any unpleasant reaction, even in young children. It appears to be as effective as the Bayer preparation "mitigal," and has the great advantage of being inexpensive.

Advertising by Medical Men in Former Days

Dr. O. B. SHELSWELL (Forest Green, Dorking) writes: Unless my grandfather was over the lines of medical etiquette of his time, of which I think him incapable, advertising by medical men seems to have been resorted to at a considerably later period than that mentioned by your correspondent in the *Journal* of December 30th, 1933, as evidenced by the following. This somewhat florid notice was found at the Bodleian Library, Oxford, in the *Oxford Journal* dated November 26th, 1803: "H. Shelswell respectfully informs his friends and the public in general that he succeeds his Uncle, Mr. Mead, deceased, at Sibford aforesaid, where the practice of Surgery, Midwifery, and Medicine will be carried on with the utmost care and attention—and he hopes to merit the approbation of those he may have the honour of attending by the strictest assiduity and attention in the different branches of the profession and on the most reasonable terms."

A Warning

A correspondent in West London writes: The police have asked me to communicate the following circumstances, in the hope of catching a crook. A man called at my house yesterday and said that he had been out of work, but had at last got it. He was, he said, a joiner by trade, and must first get his tools out (presumably from pawn). Could I give him any work? I said he could make some bookshelves for me. He agreed to do, taking measurements and giving an estimate. He then said he must have £1 for the wood. This I gave him, and never saw him again. The police office to which I applied was at Askew Road, Shepherd's Bush.

Prices of Insulin "A.B."

Messrs Allen and Hanburys Ltd and The British Drug Houses Ltd, joint manufacturers of insulin "A.B.," announce a reduction in the prices as from January 11th, as follows: 5 c.m. phials (100 units), 1s. 10d.; 10 c.m. phials (200 units), 3s. 6d.; 5 c.m. phials (200 units), 3s. 6d.; 5 c.m. phials (400 units), 6s. 9d.

Corrigendum

We are asked to correct a date given in the report of Professor Leyland Robinson's presidential address before the North of England Obstetrical and Gynaecological Society, published last week at page 18. Chapman published his book in 1733 not 1773.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 40, 41, 42, 43, 46, and 47 of our advertisement columns and advertisements as to partner-ship, assistantships, and locumtenencies at pages 44 and 45. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 15.

An Address

65

SOME ALARMING SEIZURES*

BY

JOHN A. RYLE, M.D., F.R.C.P. (LOND.)

PHYSICIAN TO GUY'S HOSPITAL.

In the course of medical practice we are confronted from time to time by peculiar "seizures" or "nerve storms," which lack conformity with the more familiar descriptions, some of these seizures cause great alarm to their victims, in that they seem to threaten paralysis, speechlessness, unconsciousness, or even death itself, or because they occasion profound states of instability and prostration. The appearance and sufferings of the patients during these attacks may further alarm relatives or onlookers, and even the medical man, unless he be familiar with the true nature of the "seizures" or fully alive to the history of the case, may be taken unawares, and feel so dubious about their purport and outcome as to be unable to give a reassuring prognosis.

And yet the seizures which I have in mind are all consistent with long life and with good health at other times. These with the more local effects may simulate or suggest organic disease of the brain; those causing serious instability may also be wrongly attributed to cerebral vascular disease or cerebral tumour; those which cause pallor, distress, disturbances of pulse rate, precordial pain or discomfort and, more rarely, loss of consciousness, are apt to be ascribed to disease of the heart. We might reasonably include in this category ordinary faints or syncope and epileptic attacks, and Gowers,¹ who did more to illumine this subject than anyone else, discussed together under the broad heading of "The Borderland of epilepsy," syncope, vertigo, and certain other "nerve storms" to be described.

Fainting and epilepsy, as being better known, I shall not consider here. The particular seizures which I wish to review include the aphasic, hemiplegic, and vertiginous varieties of migraine; vertigo, whether due to labyrinthine disease or more transient vestibular disturbance; and the so-called vasovagal attacks of Gowers. If we except labyrinthine vertigo there is no demonstrable organic basis or any of these seizures. The physical overhang between attacks, unless there be a coincidental pathology, gives

negative result. They are therefore placed in the category of the "paroxysmal neuroses." In the migrainous episodes temperament and heredity, sometimes with hypersensitiveness or allergy on the one hand, and transient disturbances of physiological equilibrium due to fatigue, worry, overstrain, constipation, or mental stress on the other, may all play a determining part. To no considerable extent the same influences play a part in increasing the liability to vertigo and vasovagal attacks. Anxiety of mind or a case not by the symptoms themselves, and the subsequent prostration when the storm is past, are apt to keep the patient in an unduly receptive state, and so prone to further storms.

It is my purpose to amplify a brief general account of these interesting, and by no means rare, neuroses with some case histories illustrating their symptomatology, and, finally, as I think you will agree, their inclusion in the list of the "alarming seizures." Thereafter I shall briefly consider a few important principles in the management of cases.

MIGRAINE AND ITS VARIANTS

If we are to study its less frequent variants we shall start with a clear image of the better-known, plain form of migraine. As commonly seen it is a disorder of the active period of adult life, affecting both sexes, depending strongly upon hereditary endowment, and showing a tendency, better marked in men than in women, to spontaneous remission after the age of 50. It is characterized by symptoms of very variable severity, and occurs in intermittent paroxysms separated by days, weeks, or months. The paroxysms come "out of the blue," and often for no apparent reason; on the previous day the patient may have felt partially well. They commonly start on waking in the morning. The first symptom may be a hemianal brow ache, or more generalized headache, but before this there is often a passing disturbance of vision. Fortification spectrum or telescopia on the one hand, or a blind patch or hemianopia on the other, are the commoner forms of aura. The headache in a case of average severity becomes more intense during the day; sometimes it is completely crippling, and necessitates retirement to a quiet and darkened room. Nausea or repeated retching and bilious vomiting follow. The patient looks pale and ill, with dark rings under the eyes. Twelve hours is a usual duration for the attack, but it may be prolonged to twenty-four hours or, more rarely, though two or three days. The patient is often left with a sense of prostration, which takes another day or two to pass. Cold fatigue, worry, eyestrain, train and motor journeys, and certain food-stuffs or beverages—notably rich or fried foods, chocolate, and eggs—are among the recognized precipitating causes. Mental workers who get little exercise are more prone to the disorder than others. The menstrual period and the menopause in women are particular times of aggravation.

Some patients escape with occasional attacks of hemianopia or telescopia; some with slight headaches which cause little or no interruption to work; some experience the more familiar attacks at one time, and at another the aphasic, hemiplegic, or vertiginous variants which I am about to describe. There are also variants of another kind, in which abdominal symptoms predominate, whether as sickness, diarrhoea, or pain, or some combination of these with a general malaise, but always tending to a periodic or intermittent behaviour, and an equivalent duration of symptoms. Sometimes the abdominal manifestations are severe enough to suggest food poisoning or an abdominal emergency. In some cases there is a vague sense of sickness or discomfort about the liver region, and a look of sallowness almost approximating to icterus. Gall-bladders have been removed in cases of chronic misdiagnosed as cholecystitis. If a barium meal examination is made during an attack of migraine or related dyspepsia the stomach is found to be inert; it may take upwards of six hours to empty, and I have seen one patient accused and another suspected of pyloric stenosis on this account.

In aphasic and hemiplegic migraine, usually on a background of the more typical ocular and abdominal symptoms, there is superimposed a confusion of speech, the patient knowing well what he wants to say, but being unable to say it. With this there may be a sense of weakness in the arm, or sensation of numbness or tingling in the hand and face of one side. More rarely there is motor weakness or even a transient paralysis. It can well be understood how "strokes" are feared, or people with the condition actually demand in such cases. The symptoms, however, pass over quickly with the rest of the storm, and leave no effects behind them. Moreover, they may occur in subjects in whom it would be impossible to

* Given to the Medical Faculty of the British Medical Association.

genuine physical instability coming on without warning and beyond all voluntary control. A conditioning physical cause is also much more likely to be operative during states of nervous tension and unrest.

Case 5.—A woman, aged 60, who had previously consulted me for other troubles of a minor kind was seized, after a period of grave family worry, with a succession of vertiginous seizures, in which she was prostrate, vomited repeatedly, and experienced much singing in the ears, especially in the left ear. She did not sleep, she was terrified by the attacks, and apparently had feared a stroke. She had lost a stone in weight since her previous visit to me a year before. The only physical finding was deafness in the left ear. The entry in my notes was "labyrinthine vertigo; aggravation by fatigue, loss of weight, constipation, and worry."

Case 6.—A man, aged 54, stated that he was well until three years previously, when something suddenly "popped" in his left ear, and he had a severe attack of vertigo. He remained liable to attacks of giddiness thereafter, in which he had to grasp neighbouring objects for support. The attacks were steadily diminishing in severity. His blood pressure was 230/140. I have never convinced myself that hyperpiesia itself (apart from a vascular lesion) could cause true vertigo. In a long series of cases of vertigo a normal or low blood pressure was found to be more common than a high one. In this case, however, I surmise that the high blood pressure may have been indirectly responsible by causing a local vascular accident.

Case 7.—A young man, who had undergone a great deal of domestic strain for a number of years, lost his mother suddenly. On the day before the funeral, and again on the morning of the funeral, he awoke with nausea and intense giddiness, the fireplace appearing to revolve to the right. There were no physical signs of disease, and in this case no deafness or tinnitus, and there was no history of migraine or tobacco excess. He had always been able to make his right Eustachian tube "click." Here the evidence for an aural contribution was minimal, and I concluded that emotional stress was the predominant factor.

Case 8.—A professional man, aged 54, who had been under my care four years previously for a duodenal ulcer, came to see me much exercised about symptoms of quite another kind. For six months he had noticed increasing deafness in the right ear. One day he suddenly collapsed with intense giddiness and violent vomiting, and thought that he might die in the attack. He had to be carried home, and remained ill all day. Four other attacks followed in the next few weeks. He was greatly relieved in his mind by the reassurance given. Three months later he reported that deafness had become complete in the affected ear, and that he no longer had any giddiness.

I could recount the histories of many other cases of vertigo in which anxiety and apprehension were much in evidence, leading in some to a bed-ridden invalidism. Whatever other contributory measures of treatment are employed, I have again and again been impressed with the value of a simple explanation and a full reassurance. Disabuse your patient of all ideas of "strokes" or of cerebral or heart disease, and you will have given him a valuable helping hand. There is no specific medical treatment of the ear disease, and the cases suitable for treatment by the neurological surgeon must remain in a minority and be selected with the most exclusive care. There is the more reason, therefore, to concern ourselves with the associated factors in the management of these cases.

VASOVAGAL ATTACKS (GOWERS'S SYNDROME)

I have mentioned the sense of impending death as an occasional symptom of vertigo. In vasovagal attacks (Gowers's syndrome) it is one of the most constant and quite the most urgent and dreaded of symptoms. These attacks affect adults of either sex and any age; they are more frequent in women than in men. In my experience the victims, almost without exception, have been affected simultaneously by a minor cause of general physical ill-

health, and by some anxiety or mental stress. As with vertigo and fainting, but for an even more imperative reason, the anxiety engendered by the attacks themselves is a strong perpetuating factor. The attacks "come out of the blue," and may last minutes, or half an hour, or for longer periods. They leave a sense of prostration afterwards. A visceral disturbance, such as vomiting or diarrhoea, a bowel wash-out, or an oesophageal or intestinal spasm have sometimes precipitated the seizure, but no such disturbance can be traced in the majority of cases.

The chief complaint is of "a sense of dying"—not a fear of death, which is sometimes even desired, so intolerable is the distress of the attacks. I have sat by the bedside and been assured by a patient that this time the end had come. In other cases of a minor kind a sense of "something dreadful about to happen," of "fading away," of "floating in space," or a peculiar "sense of unreality" are described. There is a complaint of profound malaise, of coldness, sometimes of shivering or trembling, and of heaviness, immobility, or powerlessness in the limbs, and, in these circumstances, patients have told me that even if a cup of restorative were within reach they would be unable to lift a hand to take it to their lips. This immobility is strongly reminiscent of the frozen powerlessness observed in the rabbit "fascinated" by the stoat or snake, and one patient, who had seen an animal in this state, was forcibly reminded of the incident by her own symptoms. Precordial or substernal discomfort, or genuine pain spreading into the left side of the neck and down the left arm, or a sense of constriction in the chest is common, and tingling in the finger-tips and sometimes true tetanic spasms are also described. To observers the patient looks very ill and pale, and may be cold to the touch. Even medical men have been deceived, and thought that death was imminent. The pulse may be rapid or very slow. In one case of mine it fell on occasion to 60 and once even to 19 to the minute. Sometimes the general symptoms, sometimes the cardiac symptoms, predominate, but the "angor animi" is rarely absent. These attacks are often diagnosed erroneously as "heart attacks." Some of them do, indeed, closely simulate angina pectoris. Many of the so-called pseudo-anginas in women and younger subjects are examples of Gowers's syndrome. As a rule consciousness is retained, but occasionally it is lost, and when this occurs it is for much longer periods than in the case of an ordinary faint.

Case 9.—A young man, aged 21, of outstanding energy and conspicuous fearlessness in the pursuit of sport, a motorcyclist, a member of the Auxiliary Air Force, and a keen rider to hounds, consulted me on account of attacks in which he suddenly had a feeling of impending death. These attacks had "scared him terribly." Associated symptoms included an uncomfortable feeling about the heart, an appearance of objects being "blacked out," and a "wobbly" sensation at the knees. The attacks would last from half to one hour. Three years previously he had sustained a concussion and a fractured leg in a motor accident, and had been given anti-tetanic serum. Two months previously he had sustained further injuries in another accident, and was again given serum. Serum sickness with urticaria and fever followed, and a little later he developed mumps. It was during the serum sickness that he had his first vasovagal attack. He was an excessive smoker. His father had experienced identical attacks at the age of 27, and had outgrown them. I have another example of vasovagal attacks occurring in a mother and a daughter.

Case 10.—A young woman, previously healthy and placid, underwent an operation for appendicitis. During convalescence she developed almost every morning a pain across the abdomen, followed by a bowel action. On ten or twelve occasions this was succeeded by tachycardia, feelings of dizziness or numbness in both arms, especially in the left, generalized tremor, and a most acute sense of dying. She then

remain obscure it is a matter for comfort that it lies within our power to recognize that some of the more alarming episodes of medical practice need not, in fact, occasion any fear of an unhappy ending.

THE MENACE OF HEREDITARY BLINDNESS

BY

J. MYLES BICKERTON, M.A., B.Ch.CANTAB., F.R.C.S.
 SENIOR OPHTHALMIC SURGEON, KING'S COLLEGE HOSPITAL; OPHTHALMIC
 SURGEON AND DEAN, ROYAL EYE HOSPITAL; CONSULTANT
 OPHTHALMIC SURGEON TO ST. OLAVE'S AND LEWISHAM
 HOSPITAL

The total world figures relating to blindness must be of staggering dimensions. In China one disease (trachoma) has been estimated to have blinded one million in both eyes, three to four millions in one eye, and to have gravely injured twenty millions—this out of a population of, say, 400 millions. In the United Kingdom the registered blind were reported as follows:

TABLE I

Year	England and Wales	Scotland	Total
1919	23,843	—	—
1929	52,727	—	—
1930	56,853	8,516	65,369
1932	62,433	? 10,000	? 72,727
War blind	—	—	2,000

About 8,000 of these blind are also mentally defective, and many are deaf.

There has been an increase, therefore, of 35,000-odd in the registered blind in the last twelve years, while in the year 1929-30 the increase was 4,126, or over eleven a day. The total figure, however, is by no means a true indication of our blind population, for the following groups of persons are largely excluded, and may increase it to 250,000 blind persons.

1. Almost all blind persons of the well-to-do classes.
2. Infants below school age (many die blind).
3. Those who become blind after leaving school at 14 or later, and are not registered until reaching blind pension age at 50. Many of these refuse to be certified, regarding it as rather a disgrace.
4. Those who become blind after 65 and are not registered. They obtain the old-age pension, which is the same in amount as the blind pension—namely, 10s. weekly. This is a very large group, and is likely to grow as the average length of life increases.
5. Those blind persons who are eligible for the blind pension—that is, they are between the ages of 50 and 65—but who do not apply for it because they have never heard about it.

On one random afternoon at hospital recently I saw ten persons who, although blind, were not registered, or not likely to be registered, as matters stand to-day.

The certification of the blind, however, is done in a very haphazard way in this country, and the real causation of blindness is not truly shown, so that the figures in Table II are only approximate. A child, I should explain, is considered blind if it cannot read school books with safety to the eyes; while the criterion for an adult is the capacity to do work for which eyesight is necessary.

TABLE II.—Rough Figures of Causation of Blindness in the United Kingdom*

Cause	Per cent.	Largely avoidable per cent.
Trachoma	2	2
Purulent conjunctivitis	2	1
Ophthalmia neonatorum	5	5
Accident	5	2
Congenital defects	6	6
Senile degeneration	10	—
Glaucoma	10	1
Myopia	14	14
Syphilis	15	10
Senile cataract	15	1
Others	16	2
	100	44

The 44 per cent. in column 2 may represent 70 per cent. of blind years lived. Those blind in one eye may number about one million.

Under 1 Year of Age*

Cause	Per cent.	Category
Accident	2	Neglect
Syphilis	5	Heridity
Purulent conjunctivitis	8	Dirt
Congenital defects	30	Heridity
Ophthalmia neonatorum	50	Dirt
Others	5	—
	100	—

(21 per cent. of the blind are blinded in the first year of life.)

A glance at Table II will show that blindness in the more active years of life is very largely avoidable, while much of it is due either to definitely dysgenic births or to the unrestricted production of children in poor or bad circumstances. In this table I have given the groups of the blind and the percentage in each group which could, in my opinion, be greatly reduced by certain preventive measures, since for practical purposes bad genes and certain types of bad environment may be included together as causes of blindness.

Trachoma (2 per cent.).—This disease does not occur in clean households (see China, Egypt, etc.).

Purulent Conjunctivitis (2 per cent.).—This condition rarely occurs in clean households, and in my opinion 1 per cent. is entirely avoidable (only one child in five is born into a clean home in England).

Ophthalmia Neonatorum (5 per cent.).—This disease, due to gonococcal infection at birth, could and should be entirely wiped out by the prevention of unsuitable births.

Accidents (5 per cent.).—A fair number of these occur to infants, a fact which has considerable relevance to the limitation of births. A woman explained in a South London court, for instance, that she was the only person alive and responsible for sixty-eight children (three marriages). There was recently reported a family in Buckinghamshire of thirty-nine children, and one woman, newly-married, had nine children in two and a half years (three sets of triplets). How can she manage with a husband earning £3 a week?

Syphilis (15 per cent.).—It is probable that 10 of the 15 per cent. syphilitic blind owe their condition to congenital syphilis, which might be called a "pseudo-heridity" since it never goes beyond the second generation, and which could be entirely eliminated by preventing syphilitic women from having children. Naturally, if a woman has been shown (by the Kahn, Wassermann tests, etc.) to be syphilitic, she should avoid conception at all costs, unless, and until, she has been completely cured. If, however, her condition is not discovered until after conception, the problem becomes more difficult; but treatment during pregnancy will always obtain a non-syphilitic child if the treatment is thorough and commenced about the fourth month. If treatment cannot be thorough the choice is between the birth of a congenital syphilitic and inducing an abortion, and I, for my part—

* Column I is modified from Hamman, and the other figures are my own estimates.

though I know many will not agree with me—am strongly inclined to the latter. Congenital syphilis, which shows itself in the eyes anywhere between the ages of 2 and 35 (usually between 5 and 25), is a slow and terribly distressing affliction to patient, parents, and even doctors. From two to ten years' treatment is often necessary before even a quiescent stage is reached, and it may cause blindness in three different ways: by interstitial keratitis (or inflammation) of the cornea; by a widespread choroiditis with destruction of the retina; or by juvenile optic atrophy. Needless to say, a congenital syphilitic is often ament, and is never really healthy. In my opinion, therefore, Wassermann (or other) tests should be compulsory in appropriate cases, and a positive indication should be followed by treatment, contraception, sterilization, or abortion, according to the circumstances. I have said "compulsory," but I believe that if the women of England knew that congenital syphilis, with all its terrible concomitants, could be entirely eliminated, they would welcome the appropriate routine from the medical profession. As it is, large numbers of syphilitics marry and produce defective children. At King's College Hospital last year 34 per cent. of the new syphilis cases—mostly eye cases—were congenital.

Of greater importance and interest are those types of blindness which are strictly hereditary—congenital defects 6 per cent., glaucoma 1 per cent., extreme myopia 14 per cent., senile cataract 1 per cent., other types 2 per cent.—a total of 24 per cent., or practically one-quarter of all forms of blindness. As a prelude to discussing them I should like to repeat the platitudes, too often forgotten, that normal sight (emmetropia) is also hereditary, a great number of genes being jointly at work in its production. The various departures from normality are due to the aberration of one or more members of this gene-complex.

GENETIC TYPES OF BLINDNESS

Heredity is the study of differences or variations, the laws of which show that we may all differ in three ways: (1) by modification (environment); (2) by combination in accordance with Mendel's laws; (3) by mutation, the production of new hereditary types. In certain simple forms of life 10 per cent. of the offspring are mutations; and according to Darwin's law of natural selection, the best or hardiest of these varieties survive. This variation has a beneficial effect on the community if the law of natural selection is operative. The trouble in England now is that we have dysgenic selection. Mutations act very well plus eugenic selection. They act furly well plus natural selection. They act badly minus natural selection, and very badly plus dysgenic selection. We must get back to natural selection first, and then to eugenic selection. This conclusion is logically irrefutable. Education and environment have remarkable effects upon the individual during his lifetime, but they do not influence his hereditary equipment.

We know more about the hereditary diseases of the eye than about those of any other organ, and for the good reason that, being the most important and complicated of our sense organs, its slightest defects cause marked disturbances of function.

The genetics of variations in normal eye colour are too well known—though not yet fully elucidated—for mention here, and the abnormal condition of albinism is also fairly widely recognized as a simple recessive. But the eye defects associated with albinism are not so generally realized, nor is it always understood that they are really but symptoms of a general defect. Practically all albinos are defective in the visual pathway, and with the more complete albinism the more marked the defect. This is because their eyes lack the pigment to protect the retina from light. The consequence is that they hang their heads, pucker their brows,

and half close their eyelids to shut out the light; often, moreover, they suffer from nystagmus or myopia. The incidence in the population is 1 in 10,000, and 30 per cent. of it is due, like so many similar recessives, to consanguineous marriages.

CHART 1.—Albino (Tertsch).

The Myopia Group

The genetics of this varied group have not been fully disentangled, but one can say for certain that short sight never arises in the absence of a hereditary predisposition, though that predisposition may remain latent in good health or be accentuated by illness and physical disability—as the myopia increases the eye stretches until the retina is destroyed. Dysgenic births are the chief cause of severe myopia, and many high myopes go blind, while there are immense numbers whose very defective vision is practically equivalent to blindness, but who do not come within the scope of the Blind Persons Act.

Without intending to imply, that it is a simple unit character, I must agree with Clausen, who considers that myopia tends to be recessive. Wilson, for instance, found that in 100 families with one myopic parent there were 200 myopic children and 250 non-myopic, while in ninety-one families with neither parent myopic only 100 children were myopes and 300 non-myopes. Therefore, although short-sighted offspring are often born of normal parents, when both parents are short-sighted their children invariably suffer from the same defect.

CHART 2.—Sex-linked myopia (Worth).

CHART 3.—Dominant myopia, with nystagmus (Vogt).

Wilson's figures are interesting. In 677 myopic children hereditary evidence was as follows: grandparents, 54; mothers, 369; fathers, 254; siblings, 164; uncles, aunts, 31; cousins, 9.

Father to son	79
Father to daughter	149
Mother to son	111
Mother to daughter	211

Hereditary evidence was found in 65 per cent. of low myopes, up to 3 dioptres, in 66 per cent. of medium myopes, 4 to 6 dioptres, in 67 per cent. of high myopes, 7 to 12 dioptres, and in 67 per cent. of very high myopes, over 12 dioptres. It was also found in 65 per cent. of

school children, 63 per cent. of home workers, 68 per cent. of factory workers, 60 per cent. of clerks, and 60 per cent. of labourers. The run of the figures in these last groups indicates independence of environment.

Reference must be made here to detachment of the retina, which is a fairly common sequel to high myopia. Bogatch reported a family of eleven high myopes, in seven of whom detachment of the retina supervened in one or both eyes. Retinal detachment is found as a dominant, recessive, or male sex-linked in different pedigrees.

In the same way astigmatism, long sight, and squint (which is often associated with long sight) may be inherited. Squint, from which more than 2 per cent. of school children suffer, is responsible for a large number of blind eyes.

CHART 4.—Long sight-squint (Clausen and Bauer).

CHART 5.—Hereditary nystagmus (Holm).

Microphthalmia, or very small eye, with anophthalmos (lack of an eye) as the extreme form, has been found as a dominant, recessive, or recessive sex-linked (Ash).

CHART 6.—Microphthalmia (Ash).

Retinitis Pigmentosa

Czellitzer says that nearly 4 per cent. of all the blind are due to hereditarily determined atrophy of the retina. Some 300 pedigrees are given in the *Treasury of Human Inheritance*. The condition begins in early youth and progresses to complete blindness sooner or later, often round the age of 40. As in other diseases, there are several forms, as shown by their different heredity, the commonest being recessive; 33 per cent. of those thus affected owe their condition to consanguinity. In some families the condition is linked with deafness.

CHART 7.—Retinitis pigmentosa (Sambuc).

CHART 8.—Retinitis pigmentosa (Mooren).

CHART 9.—Retinitis pigmentosa (Mann). Leber's optic atrophy.

Optic Nerve Atrophy and Optic Neuritis

These frequently cause blindness, and the hereditary variety is well recognized by ophthalmologists, 1,000 pedigrees being available for study; 85 per cent. of those affected are males. The disease comes on at different ages, the average being about 20. Diminution of vision is the chief symptom, and often appears suddenly; there is a central scotoma, and after six months or so the disease remains stationary. The malady has been traced once through six generations, twice through five generations, and often through four generations. Leber's optic atrophy is a name for the sex-linked variety. It appears to be an abiotrophy, or lack of vital force, occurring at the prime of life.

CHART 10A.—Hereditary optic atrophy (Hawkes).

CHART 10B.—Hereditary optic atrophy (Bickerton, 908).

CHART 11.—Hereditary optic atrophy (Thomsen, 802).

CHART 12.—Hereditary optic atrophy (Norris, 750).

CHART 13A.—Hereditary optic atrophy (Norris, 881).

CHART 13a.—Hereditary optic atrophy (Hogg, 837).

Aniridia

All cases of aniridia (absence of the iris) that I have seen have been of blind standard. I particularly wish to call attention to the Risley pedigree (1915) of aniridia: one blind man with this affection had thirteen children similarly affected (100 per cent.), sixty-one grandchildren out of sixty-three, and thirty-nine great-grandchildren out of forty-two (Chart 14).

Congenital Cataracts and Senile Cataracts

These are usually dominant, and are very important; Macklin states that 13 per cent. of the pupils in blind schools are blind through cataract, and Hirst gives 10 per cent. in 1,300 blind persons (anophthalmia and microphthalmia being next) (Charts 15 to 17).

CHART 15a.—Lamellar cataract (Nettleship).

CHART 16b.—Cataract (Loeb, 22)

CHART 16c.—Cataract (Henneman, 20 L.)

CHART 17a.—Cataract (Loeb)

CHART 17b.—Corniform cataract (Nettleship).

Ectopia Lentis

Ectopia lentis (congenital displacement of the lens) has been traced as a dominant through six generations, though in some pedigrees it is recessive. Cameron's pedigree shows both lenses affected in each case.

CHART 18.—Hereditary dislocations of lens (both) (Cameron).

Glaucoma

In this group the hereditary factor is not always very marked, though congenital glaucoma does occur, and there is a probable hereditary predisposition to it in many other cases. This is known as hereditary anophylaxis, or abiosis—a lack of vital force, which causes the structure to die before its time. Many pedigrees suggest a dominant heredity, but the hereditary course is occasionally interrupted, and casual causes are often necessary to bring out the disease. It may arise early in life as a juvenile glaucoma.

CHART 19.—Inflammatory glaucoma (Howe).

CHART 20.—Juvenile glaucoma (Kamenetzki).

CHART 21.—Glaucoma (Bickerton, 1932).

Blue Sclerotics

This is a condition in which the coat of the eye is too thin or too transparent, accompanied by a failure in development of connective tissues. It is often associated with fragilitas ossium, or brittle bones, and with a type of deafness due to otosclerosis. The female is more likely both to show and to transmit it. Seventy-three pedigrees since 1903 show 463 defective individuals; it is usually dominant. Of adults with blue sclerotics 60 per cent. had liability to fractured bones, 60 per cent. had otosclerosis, and 44 per cent. had all three defects.

CHART 22.—Blue sclerotics. \times = Fragilitas ossium (Burrows). Otosclerosis 40 per cent.*Glioma*

This is a rare malignant growth, occurring in infants, of the nerve elements of the eye, which in some families shows a strong hereditary tendency, and is apparently recessive. It often affects both eyes (25 per cent.), and their early removal is necessary to save life. Some sufferers survive, marry, and often transmit the defect. Mohr considers the condition to be lethal in a homozygous condition. The death of a child with glioma of the retina is an appalling experience for parents and child, and may take as long as two years. The law which forces us to withhold euthanasia in these cases at the same time forces us to act in a barbarous and monstrously inhuman fashion, and is, in my opinion, indefensible.

CHART 23.—Glioma retinae (Newton, 339).

CHART 24.—Glioma (Wilson, 349).

CHART 25.—Glioma (Thomson and Knapp, 335).

CHART 26a.—Glioma (Griffith, 333).

CHART 26b.—Glioma (Letchworth, 1898).

Maculo-Cerebral Degenerations

Several conditions might be described under this heading, including the rare disease of the central nervous system known as amaurotic family idiocy. Commencing at about 5 or 7 years of age, the children go blind within two years and mentally degenerate within the next two; death occurs about the age of 17 or 18. Amaurotic family dementia is a diffuse tapeto-retinal degeneration causing total, or nearly total, blindness, beginning at

birth or later, and frequently associated with cerebral degeneration producing idiocy. It is a not infrequent cause of congenital blindness.

CHART 27A and 27B—Amaurotic family idiocy (Sedgwick).

CHART 27—Amaurotic family idiocy—"Tay Sack" (King, Rus, Stewart).

Night- and Day-Blindness

Night-blindness is due to a defect of the rod vision (colourless vision). At dusk these cases are blind, though their sight is normal in good daylight. The famous Nongaret pedigree, by Nettleship, shows 135 affected persons out of 2,116 in nine generations (a dominant heredity). There are also a recessive sex-linked type, which is regularly associated with myopia, and one or more simple recessive types (Switzerland, Japan).

CHART 28—Progressive night-blindness. Death sixteen months after complete blindness (Bordley).

CHART 29—Stationary night-blindness (Sedan).

Day-blindness is a cone vision defect; such cases are colour blind and also of "blind standard."

CHART 30—Day-blindness (Hedberg).

CHART 31—Day-blindness (Hedberg).

POSSIBLE REMEDIES

The cost in misery and unhappiness of this state of affairs is appalling, and the cost in money (potential happiness) runs into millions. Are we justified in looking on complacently or are we blameworthy? Our aims are to prevent blindness by improving environment and heredity. Here are some of the means available.

1. Constructive birth control to avoid overcrowding and poverty.

2. Sterilization of mental defectives (and possibly certain criminals) as in America.

3. Review of the obsolete and ancient abortion laws, seventy years old. They are no longer effective, and are acting deleteriously and dysgenically. Abortion should act as a second line of defence to conception control, as in Russia.

4. Euthanasia for infants with gross defects to be available for parents who wish to make use of it.

5. Segregation of the mentally defective is difficult owing to the cost; some 300,000 are now at large.

6. The Catholics recommend control of marriage for the mentally defective, but this does not prevent illegitimacy.

7. The Wassermann reaction during or before pregnancy. This is done in Rumania before marriage.

In Mexico the State of Vera Cruz has put into effect laws for the legalization of birth control, sterilization of certain criminals and mental defectives, prevention of hereditary ailments where practicable, and the prevention of marriage by persons who are mentally deficient or physically or economically unfitted to have children. How long must we in England continue with our present inhuman methods?

THE CLASSIFICATION OF THE BODY CONSTITUENTS BY WATER CONTENT*

BY

HAROLD G. CLOSE, M.D. LOND.

ASSISTANT BACTERIOLOGIST AND LATE GRIFFITHS DEMONSTRATOR OF
PATHOLOGY, GUY'S HOSPITAL

For the sake of convenience it has been customary to describe the body by regions (anatomy), systems (physiology), or origin from embryonic layers (embryology), but for biochemistry there appears to be no such simple grouping. To remedy this deficiency a classification based on water content has been made and is presented here. Water deserves to be singled out for distinction because of its unique position in the economy of the body, both in the past and now. Besides being at one time the only medium in which life existed, it now forms the greater part of all living tissues, and plays an essential part in most, if not all, biochemical reactions. The data from which this classification was derived were obtained partly by estimations made on the chloride and water of tissues, and partly from the literature, and have been published elsewhere.¹ Unfortunately, there are still many gaps in our knowledge, but it is possible even now to see the outline of the pattern underlying the construction of tissues.

THE THREE TISSUE GROUPS

If the parts of the body are considered from the point of view of their water content they will be seen to fall naturally into three groups.

A. The body fluids (extracellular).

B. The nuclear or cellular tissues.

C. The anuclear, "matrix," or supporting tissues.

* Formed part of a thesis approved by the University of London for the degree of Doctor of Medicine.

These are shown with their range of water content and the principal members of each group in Table I.

TABLE I.—Water Content and Designation of Three Tissue Groups

Name of Group	Member	Range of Average Water Content
A. Body fluids (extra-cellular)	C.S.F., lymph, plasma, synovial fluid, etc.	Per cent. 90 to 99
B. Nuclear (or cellular) tissues	Grey matter of nervous system, glands, muscles	76 to 85
C. Annuclear (or supporting) tissues	Connective tissue, cartilage, bone, white matter of nervous system	10 to 13

The upper limits of some of the nuclear tissues may overlap with the lower limits of water content in several of the nuclear tissues, so that actually the division between Groups B and C is not so clear-cut as between Groups A and B. On the other hand, there are important points of difference between nuclear and anuclear tissues. The reaction (pH) of tissues of Group B is kept constant by the phenomenon of "buffering"—a property anuclear tissues do not appear to possess.² Then the types of protein in these groups also differ—mainly nucleo-protein in the nuclear, and gelatin derivatives in anuclear tissues. But these and other characteristics may perhaps be secondary to the main distinction between the two groups—namely, the presence or absence of many nuclei. Tissues with many nuclei (Group B) contain more water than those with few, and this relationship of the nucleus to water content is seen in a striking way in cells which ultimately lose their nucleus. For example, the water content of a young nuclear red blood cell is 75 per cent.; when mature and anuclear, the red cell contains only 65 per cent. of water. The rate of metabolism of a tissue also appears to be related to the presence of the nucleus. First, there are reasons for believing that the nucleus is closely associated with the respiration of the cell³; and secondly, the rate of metabolism in the highly cellular nuclear tissues is far greater than in the supporting tissue group (C). Warburg⁴ was very doubtful if respiration or glycolysis occurred at all in this latter type of tissue. It may be said, therefore, that the greater the rate of metabolism in the tissues the higher is the water content, a principle which is seen in the process of growing old, when there is a parallel decline in both water content and active metabolism.

THEIR INTERRELATION

The relationships in the three groups between the water, chloride, hydrogen-ion concentration, sodium, potassium, and protein contents are shown diagrammatically in the figure, and summarized later in Table II.

Diagram Showing the Relationships of the Water, Chloride, Acidity, Protein, Sodium, and Potassium Contents in the three Groups A, B, and C

Abscissae = From 50 to 100 per cent. water. Ordinates = From 0 to 5 grams of chloride per 1,000 grams of water.

Chloride and Water

In Groups A and B it is found that with an increasing amount of water there is an increasing amount of chloride. In Group C, on the other hand, this rule is reversed—with an increasing amount of water there is less chloride. No adequate reason can be given at present for this difference of chloride and water relationship in Group C, though one or two suggestions may be made. For example, it appears that the red blood cell (Group C) is enabled to hold more haemoglobin by virtue of its relatively high chloride content (Green³). Also, if the gelatin-like proteins of the connective tissues exhibit imbibition pressure rather than osmotic pressure (as is not unlikely they do), a relatively increased amount of a salt such as NaCl would decrease the tendency of the protein to "imbibe," and less water would be present. But perhaps a simpler explanation may be offered. The comparative increase of chloride with less water may be due simply to a concentration effect.

Protein, Water, and Chloride

The weight of a tissue is made up of the weights of the water present and of the so-called "solid" portion, most of which is protein. Consequently the more water there is the less protein there will be. As we know the relationship between the water and chloride in the body (see above), we can say what the relationship between the chloride and protein contents will be. In Groups A and B (body fluids and nuclear tissues), with more chloride there will be less protein; in Group C (anuclear tissues), with more chloride there will be more protein. Generally, speaking, these relationships are found to agree with the facts, except in the case of liver tissue and white matter, both of which are rich in lipid bodies.

Water and Hydrogen-ion Concentration

Evidence is accumulating for the belief that the amount of chloride in a tissue or body fluid varies inversely with the hydrogen-ion concentration—that is to say, the more chloride there is, the more alkaline the tissue. Referring again to the chloride and water relationship, we may presume that in the body fluids and nuclear tissues (Groups A and B) as the amount of water increases, the acidity (or cH) becomes less—that is, alkalinity increases; in the anuclear tissues (Group C) increase of water is associated with an increasing degree of acidity.

Water, Sodium, and Potassium

As the amount of chloride in a body fluid or tissue tends to vary directly with the amount of sodium and indirectly with the amount of potassium, we have once again an indication of how the sodium and potassium contents are related to the water content in the three groups. Sodium increases, potassium decreases—with increase of water in Groups A and B, but with decrease of water in Group C. One important exception must be noted. The red blood cell, though classed in the anuclear group, has a relatively high chloride content and contains potassium, but no sodium.

DISCUSSION AND SUMMARY

These relationships, when grouped together as in Table II, indicate broadly how tissues and fluids arising from one cell have acquired their present chemical composition in the process of being differentiated. When more definite knowledge of the constitution of tissues becomes available it should be possible to formulate the laws which we now know exist. Marked variations from these laws might then throw light on disease processes, and particularly on the problem of selectivity of a disease for a certain tissue. It might even be an advantage to go back to the former classification of a tumoral and

cellular pathology, but with now an additional type—"matrical"—for diseases peculiar to the supporting or "matrix" tissues. Classified under the last-named heading would be such diseases as arthritis, fibrositis, neuritis, etc., about which little is known except that their pathology is unlike that of the other group diseases. But since each of the three groups A, B, and C has its own characteristic make-up (as shown above) it is not surprising that manifestations of abnormality should also be different.

The table shown below summarizes the findings discussed in the text.

TABLE II.—Summary

	A Body Fluids	B Nuclear Tissues	C Anuclear Tissues
Water percentage ...	50 and over	76 to 85	Below 75
Rate of metabolism ...	Nil	High	Low
Concentration of chloride ...	High	Low	Midway between Groups A and B
Relationship of chloride to water ...	Increases with increasing water percentage	Decreases with higher water percentage	Midway between Groups A and B
Relative reaction ...	More alkaline	More acid	Midway between Groups A and B
Na	High	Low	"
K	Low	High	"
Protein	Low	Midway between Groups A and C	High

Elsewhere I have acknowledged with gratitude the help received from many friends and from the Medical Research Council. I am also indebted to an anonymous donor for providing the greater part of the expenses of this investigation.

SYMPATHETIC GANGLIONECTOMY FOR GANGRENE DUE TO THROMBO- ANGITIS OBLITERANS

BY

H. HAMILTON STEWART, M.A., M.B.,

B CHIR. CAMB., F.R.C.S.

HONORARY ASSISTANT SURGEON, BRADFORD ROYAL INFIRMARY;
HONORARY SURGEON, BRADFORD CHILDREN'S HOSPITAL

The value of sympathetic ganglionectomy for the treatment of Raynaud's disease is well known, but doubt is still expressed as to its value in the treatment of thrombo-angitis obliterans, or, as it is often called, juvenile gangrene or Buerger's disease. It is the purpose of this paper to give a brief description of this rather rare disease and to record a case treated successfully by sympathetic ganglionectomy.

THE DISEASE

The cause of thrombo-angitis obliterans is unknown. It usually occurs in young males between the ages of 17 and 35, and was originally considered to be almost limited to the Hebrew race; this has now been shown not to be the case. Over-indulgence in tobacco has been said to be a determining factor, but there is little evidence to support this theory. Buerger¹ originally suggested an inflammatory or toxic origin, and workers at the Mayo Clinic² have performed experiments which tend to support this view. In this disease thrombosis occurs in the larger arteries of the limbs, and, if the arterial system is extensively involved, gangrene is liable to occur. The capillaries, often des, and forest arteries appear to escape. The thrombosis may affect the whole or only a portion

of an artery at one time, but recurrences of the thrombosis will occur, now in this, now in that artery, until the signs of deficient blood supply to the limb become evident. The thrombus is eventually organized, and may be recanalized, and with this process some degree of periarteritis is prone to occur. The veins of the limbs may be affected in the same way.

It is interesting to note that the actual thrombosis would appear to pass unnoticed by the patient, and to be free from constitutional reactions. This was so in the case I am about to describe, even though the patient had suffered from the disease in three of his limbs and was warned that the last one might be affected in the same way. It is not until the obliterative process has extended so widely as to interfere materially with the blood supply of the limb that the characteristic symptoms of the disease become manifest. The patient suffers from the result of the disease rather than from the disease itself. He (or she) complains in the first instance of a sensation of numbness and coldness in the affected limb in the cold weather, and indefinite pains, which he often considers to be rheumatic in origin. These affect particularly the arch of the foot, calf of the leg, and the wrist. The symptoms of intermittent claudication are complained of quite early in the history of the disease, and when the affected limb is allowed to hang down the extremity acquires a purplish blush, which gives place to excessive pallor on elevation of the limb. Degenerative changes occur in the skin and nails, the skin becoming thickened and cornified and the nails brittle and hard. Ulceration is prone to occur under the nails and in any site of local injury. Later, the patient suffers from persistent pain, and sits holding the affected limb. Gangrene eventually supervenes. On examination the affected limb is cold, and if the progress of the disease has been slow some wasting is evident. It may not be possible to feel pulsation in such arteries as the dorsalis pedis, posterior tibial (at the ankle), popliteal, radial, and ulnar arteries.

It is difficult at first to understand how sympathetic ganglionectomy can improve the blood supply to a limb when the larger arteries are blocked with organizing thrombi. It would appear to act by allowing the smaller arteries to dilate and thus improving the collateral circulation. The value of periarterial sympathectomy is known to be transitory. Now if satisfactory results are to be obtained the appropriate sympathetic ganglia corresponding to the limbs must be removed. In the case here recorded the inferior cervical and first thoracic ganglia were removed on both sides by an exposure obtained by costo-transversectomy at the level of the second rib. In this operation the transverse process of the second thoracic vertebra is removed along with about three inches of the second rib. The pleura is then depressed and a good exposure of the sympathetic chain with its branches is obtained, rather better on the left than on the right side. The desired amount of sympathetic tissue can be removed exactly, and the risk of leaving a portion of the first thoracic ganglion behind is very small. The anterior approach is difficult, the exposure often inadequate, and an incomplete operation is liable to result.

The case described below is that of a young man, aged 25, a gentile, who had lost both lower limbs from gangrene due to Buerger's disease, and who was in imminent danger of losing both upper limbs from the same disease. By a timely sympathetic ganglionectomy on both sides it was possible to save these limbs.

CASE RECORD

The patient comes of a healthy family, and with no history of syphilis on two occasions his Wassermann reaction was negative. At school he was the fastest runner, and was in perfect health until February, 1925, when at the age of 18 a box fell on his right foot. A phlebitis resulted, which

prevented him from working for ten weeks. During the next three years he limped slightly, and experienced "tightening feelings" in the right calf, with stiffness on occasions. Eventually pain occurred in the calf on exercise, and he was unable to walk far without resting. His foot was cold in the winter months. In October, 1928, he complained of persistent burning pain in the right big toe, and he was admitted to hospital with commencing gangrene of this toe. In spite of periarterial sympathectomy and removal of the toe, amputation through the right thigh was necessary in May, 1929. In April, 1930, a similar series of symptoms occurred in the left lower limb, and in November, 1930, amputation through the left thigh was performed.

November, 1931, marked the commencement of trouble in the left upper limb: The hand began to perspire excessively and itch, and the fingers became cold and dead when exposed to the cold air. The condition of the hand became gradually worse, and by February, 1932, there was spreading moist gangrene of the little and ring fingers, and the pulp of the terminal phalanx of the thumb. The patient was in persistent pain, and sat holding his hand. The pulse could not be felt in either radial or ulnar arteries.

The inferior cervical and first thoracic sympathetic ganglia on the left side were removed under general anaesthesia by the route described. While the ganglia were being dissected away the pulse rate became rapid (135), but settled again after interference with the sympathetic had ceased. Recovery was uneventful. The typical signs of sympathetic loss to the head and upper limb on the left side were evident. There was a pin-point pupil, enophthalmos, increase of surface temperature, and absence of sweating to a sharp line of demarcation at the level of the second thoracic segment. For some few days after the operation near vision was misty, and, on reading, the words split into syllables. Distant vision was normal. The effect of the operation upon the hand was excellent. The pain disappeared immediately and the hand became warm. Lines of demarcation occurred, and the gangrenous portions were removed. The gangrenous part of the pulp of the thumb separated and the terminal phalanx was left healthy.

The patient makes the astounding statement that in the following summer he worked his wheel chair to Morecambe and back, a distance of 120 miles, during a week-end! He experienced no trouble with his upper limb, in spite of the hard work entailed. In December, 1932, he was examined, and the condition of the left upper limb was found to be very satisfactory. A faint pulse could now be felt in the radial artery. In the beginning of 1933 the circulation in the right upper limb became defective and gradually deteriorated, and in April, 1933, after knocking his index finger, septic lesions occurred which failed to heal. The hand became painful and the fingers purplish in colour. The pulse could not be felt in the radial or ulnar arteries.

In June, 1933, the inferior cervical and first thoracic ganglia were removed on the right side by the posterior approach, as before. Recovery was uneventful, and the result of the operation excellent, as on the other side. He was discharged from hospital three weeks after operation, and is at the present time (November) carrying out his work as an artificial flower maker.

SUMMARY

1. A brief description of thrombo-angiitis obliterans, or Buerger's disease, is given.

2. A case is described in which both upper limbs were saved from gangrene by sympathetic ganglionectomy. Both lower limbs had been lost previously from the disease.

3. The posterior route through the chest, for the removal of the inferior cervical and first thoracic ganglia, is considered to be better than the anterior approach. The exposure is superior, and incomplete removal of the first thoracic ganglion, liable to occur by the anterior route, is by this means unlikely.

4. Removal of these ganglia on both sides was not accompanied by any permanent ill effects on the brain, eyes, or heart.

I am grateful to Mr. Goyder for permission to publish this case, which was under his care.

RELATION OF THROMBOPHLEBITIS MIGRANS TO THROMBO-ANGIITIS OBLITERANS

BY

A. L. D'ABREU, M.B., Ch.B., F.R.C.S.

ASSISTANT IN THE SURGICAL UNIT OF THE WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF; LATE SURGICAL REGISTRAR, GENERAL HOSPITAL, BIRMINGHAM

In this country thrombophlebitis migrans is usually regarded as a malady quite separate from the general vascular disease known as thrombo-angiitis obliterans. Buerger¹ insists that phlebitis migrans is part of a widespread disease affecting both veins and arteries. He states: "The association of thrombosis of superficial veins of the upper and lower extremities with other evidence of obliteration of the larger arteries occurs in a sufficiently large number of cases to make the affection of the veins almost pathognomonic." After a full description of a series of these cases some of his conclusions are as follows:

1. The disease thrombo-angiitis obliterans is often associated with thrombophlebitis of the superficial veins of the arms and legs.
2. The clinical disease of the superficial veins may be subsiding or it may dominate the clinical picture. . . .
3. Migrating thrombophlebitis may give no symptoms, the signs referable to the deep vessels being of most importance.
4. Patients may suffer at one time from migrating thrombophlebitis, at another from the progress of the occlusive changes in the deep vessels.

He found that in all cases of thrombophlebitis migrans which he studied, the pulses eventually became imperceptible. He based these conclusions upon exhaustive clinical and pathological examinations of limbs, many of which required amputation, and found that both superficial and deep veins, in addition to the arteries, exhibited those curious inflammatory and thrombotic changes so typically seen in thrombo-angiitis obliterans.

In this country we have been slow, or perhaps reluctant, to recognize the apparent unity of the disease processes. Moorhead and Abrahamson² in 1928 described phlebitis migrans as a new disease complex, because in their four cases visceral as well as superficial veins were involved. They write: "It is interesting, though perhaps inapposite, to draw attention to cases quoted by Buerger in which recurrent phlebitis of superficial veins was the precursor of thrombo-angiitis obliterans. Such a sequel has not been encountered by us, and it is likely that Buerger's cases did not belong to the group with which we are dealing." The case described below is reported because the patient for many years clearly belonged to the group described by Moorhead and Abrahamson, with migrating thromboses that involved visceral and superficial veins, and yet ultimately he presented all the features of thrombo-angiitis obliterans, from which he died.

A. B. Walker³ in 1932 published a paper on thrombophlebitis migrans, and collected fifteen cases in which, up to that time, apparently no arterial disease coexisted; he quotes, however, a case recorded by Campbell and Morgan⁴ in which apparently a thrombosis of the posterior cerebral arteries accompanied multiple venous thromboses elsewhere. N. Kletz,⁵ in recording cases of migratory phlebitis, mentions the association with thrombo-angiitis obliterans; he utters the important warning that "though the prognosis has been regarded by most writers as uniformly favourable, this is not so." He records a fatal case, and to this may be added the one described below. F. Parkes Weber⁶ refers to a case he recorded with Schwarz in 1908 under the heading of "Arteritis Obliterans of the Lower Extremity." The patient subsequently developed the typical symptoms of thrombophlebitis

migrans. In the case recorded below the venous thromboses preceded by many years the objective signs of arterial involvement.

CASE REPORT

A man, aged 52, a country mason and married, was admitted to the General Hospital, Birmingham, under the care of Dr J. M. Smellie, on February 7th, 1933, for the investigation of migratory thromboses of wide distribution and of many years' duration. The first attack of phlebitis occurred when he was 12 years old, in the left leg. He was admitted to St Thomas's Hospital, London, eight years later, when portions of the left internal saphenous vein were removed. There were frequent recurrences of phlebitis, and on the outbreak of war he was certified as unfit owing to the condition of his legs. In 1914 the superficial veins of the abdomen were attacked by painful thromboses, and became dilated and obvious. By 1927 the condition had improved somewhat, but attacks of phlebitis in the legs and on the abdominal wall were frequent. In 1931 severe exacerbations forced him to bed for three months. During this period and in the preceding years he had many attacks of haemoptysis, mild in degree with no apparent cause, but associated with some pain in the chest. He continued to improve and relapse periodically until his admission to hospital in 1933.

On examination he was a well-built man of healthy appearance, apyrexial, with a blood pressure of 142/78, and a regular pulse of 76 to 80 beats per minute. The lungs and heart were free from physical signs of note. Both legs showed dilated tortuous veins, with a scar in the right thigh from the operation thirty-two years ago, and with many areas of healed thrombosis on both sides. The abdomen was traversed by dilated superficial veins with evidence of old clotting, but now free from recent thrombosis. A full investigation was carried out: the blood count was normal; there was no leucocytosis; the van den Bergh test, a blood sugar tolerance curve, a gastric test meal, and the Wassermann reaction were all within normal limits. No source of sepsis could be found on clinical or radiological examination. He was discharged with a diagnosis of "thrombophlebitis migrans," and a good prognosis was given.

Readmission and Operation.—On March 28th, 1933, he was readmitted to the hospital, twenty-four days after his discharge. He was complaining of severe cramp-like pains in the right hip and the right foot, the latter showing purple discoloration up to the middle of the dorsum. The foot was cold, and showed slight oedema. The right femoral artery pulsated, but the pulse in the popliteal and dorsalis pedis arteries was imperceptible. A lumbar sympathectomy was considered, and an intravenous T.A.B. vaccine test was done: the fact that although the general body temperature rose to 101.8° F. the temperature of the affected limb scarcely rose (78.8° F.) contraindicated sympathectomy. The pain became excruciating, and required large doses of morphine for its relief. As the gangrene began to spread, at the direction of Professor Seymour Barling I amputated the leg through the middle of the thigh by means of equal anterior and posterior flaps, in view of the diseased state of the vessels no tourniquet was employed, but the bleeding was extremely slight. The large veins contained organized clots, and the femoral artery showed severe occlusive changes.

Progress.—Two days after the operation severe pain commenced in the left foot, which became cold, numb, and discoloured, with signs of incipient gangrene; the pulse in the popliteal and dorsalis pedis arteries became imperceptible. Six days later the flaps in the amputated limb broke down, and consequently the patient developed a severe hypostatic pneumonia, from which he died twelve days after operation.

The Post-mortem Findings.—The heart was normal, with no disease of the coronary arteries: the aortic arch showed only atheroma. The lungs contained patches of bronchopneumonia with many small darkened areas suggestive of recent infarcts. The only evidence of vascular disease in the brain was a small area of old softening in the left optic chiasm. An unexpected finding was a complete fibrotic atrophy of the left lobe of the liver, with a compensatory enlargement of the right lobe. The localized affection of the liver suggested a vascular cause. The other abdominal organs were normal. The vessels of the abdomen were carefully examined: the aorta and the inferior vena cava were found to be affected by inflammatory fibrous tissue, which

included many enlarged lymph glands. This inflammatory matting of artery and vein extended down into both lower limbs. On slitting up the aorta a ragged mass of ante-mortem thrombus stretched from a point three inches above the bifurcation; as this was followed down, the large vessels of the arterial and venous systems, from the common iliacs downwards, were found to be completely thrombosed. The inflammatory and thrombotic changes were unusually extensive, although Buerger reports cases involving the aorta. Telford and Stopford⁷ record that at operation for a perforated duodenal ulcer in a patient known to be suffering from thrombo-angiitis obliterans, the left common, internal, and external iliac arteries were palpated as pulseless immobile cords.

Histology of the Vessels.—The veins showed organized and canalized thrombi, and the arteries a similar process, both recent and old. The appearances were typically those described so exhaustively by Buerger, and the inflammatory background of the pathological state was well marked.

COMMENTARY

This patient had for forty years suffered from migrating thromboses: these involved the legs, the superficial veins of the abdomen, and the lungs, as shown by the attacks of haemoptysis (haemoptysis occurred in three of the four cases reported by Moorhead and Abrahamson). The onset of severe pain in the leg, succeeded by gangrene, the findings at operation and in the post-mortem room, and the histological appearances of the vessels leave no doubt that the ultimate diagnosis of thrombo-angiitis obliterans was correct. This conforms with Buerger's extended experience of these cases. A diagnosis of "thrombophlebitis migrans" seems to be an inadequate one, and may carry with it a false prognosis of benignity. Perhaps recorded cases of "thrombophlebitis migrans" in English literature, if observed over sufficiently long periods, may be seen ultimately to belong to the wider class of "thrombo-angiitis obliterans." Because of the somewhat doubtful position of "thrombophlebitis migrans" in vascular pathology, it is thought that this case should be reported.

I am grateful to Dr. J. M. Smellie and to Professor Seymour Barling for permission to publish these notes; to Dr. F. Mason Lamb, who conducted the post-mortem examination, which I attended, and who reported on the histology of the vessels; and to Dr. A. Brian Taylor for his helpful co-operation.

INCREASED INTRAOCULAR TENSION IN YOUNG PERSONS AS A CAUSE OF SEVERE FRONTAL HEADACHE

BY

R. L. RAYMOND, M.B., CH.M.
FLIGHT LIEUTENANT R.A.F.M.S.

The four cases to be described are published in the belief that they represent a symptom-complex which is not commonly recognized. Each of these patients came complaining of frontal and temporal headache of varying degree and radiation; each was a young man between 20 and 30, and before the typical glaucoma age. In each case frontal sinusitis, tic douloureux, incipient herpes ophthalmicus, migraine, etc., were considered, and as far as possible eliminated. In each case the pain was increased by pressure on the eyeball, and the tension of the eyeball, as estimated by digital examination, was thought

to be higher than that in the other eye. There was no other constant abnormality in the eyes. The pupils, except in one case, were equal and round, and reacted equally to light. Visual acuity was normal to the individual patients. Cases 1 and 2 resented the glare of the ophthalmoscope, and I was unable to see the disk. Homatropine was avoided for fear of increasing the symptoms. I have since examined the fundi of each case under homatropine. Acting on the assumption that this increased intraocular tension might be the cause of the referred neuralgia, eserine was instilled into the eye in each case, with the results presently to be described in the following extract from the case notes.

CASE RECORDS

Case 1.—A. E. B., an officer, aged 27, complained of intense headache over right frontal and temporal region for twenty-four hours. Pain continuous, with exacerbations. No tenderness over frontal sinus. Nasal mucous membrane normal. Raised intraocular tension present. Pain increased by pressure of examination. Admitted to hospital at noon as probable onset of herpes ophthalmicus. Symptomatic treatment of raised tension by eserine drops, half-hourly for three instillations, and thereafter enough to keep the pupil contracted. By evening neuralgia was distinctly less. At this time anterior chamber was thought to be slightly shallower than on healthy side. Aspirin-phenacetin-caffeine powder was given to encourage sleep. Next day one A.P.C. powder was given to relieve pain of eserine instillation: tension was less. The third day pain had quite gone, and tension was thought to be slightly less than that of other eye. Patient kept under observation for three days. Herpes did not develop. There has been no recurrence of the neuralgia. When examined under homatropine six weeks later the disks were quite normal.

Case 2.—R. E. C., soldier, aged 25, complained of left frontal headache of moderate severity for three days. Awake at night. No previous history of similar attacks. Left pupil smaller than right. Definitely increased intraocular tension, and increase of pain on pressure of examination. Anterior chambers equal in depth. Treatment as above by eserine. A.P.C. powder given on two occasions to relieve pain of eserine instillation, which was distinctly differentiated by the patient from pain of the neuralgia. Tension equal to that of other eye, and pain all gone by third day. Pupils equal. When examined five days later under homatropine there was slightly more cupping of disk than in right eye, and very slight bending of vessels. Visual acuity 6/6. Examined five weeks later, disks were normal: cup 4 D in depth in each eye. No recurrence of pain.

Case 3.—N. M., an Indian servant, aged 30, had severe pain over right brow and in temporal region extending to behind right ear and over mastoid process: no complaint of eye at all. Has suffered off and on with this for eighteen months; treated at various times at other hospitals without relief. No tenderness on pressure over frontal sinus or mastoid. Nothing abnormal detected, except slightly raised tension in right eye and increase of pain on pressure. Anterior chambers equal in depth. Eserine only was used in treatment, and A.P.C. deliberately withheld to avoid confusing the issue concerning the cause of removal of pain. Next morning patient reported quite free from pain, and with tension equal in both eyes. He was genuinely pleased at the success of the treatment after so many months of disappointment. He was kept on eserine for four days, and has not had recurrence of pain since. Examined under homatropine ten days later, right pupil dilated considerably less than left pupil; both had two lamellae of homatropine, with twenty minutes' interval. Fundi and disks were normal. Three months later he had no recurrence of symptoms.

Case 4.—A. C., a soldier, aged 28, complained of continuous, slight to moderate, bilateral frontal headache, rather worse on left side, for three weeks. Pain radiated to the occipital region. Visual acuity normal. Anterior chambers normal in depth. Pupils equal and reacted. Definitely raised tension in both eyes, especially left. Increase of pain on pressure in left eye only. One week ago was freely purged with salines for three days, and A.P.C. given at night. Temporary relief, but now headache is as bad as ever.

Admitted to hospital; eserine instilled into left eye only, t.d.s. Next day pain gone from left side of head, but rather increased on right side. Tension less on left side than right now. Eserine instilled t.d.s. into both eyes. Next day all pain gone, but a heavy feeling in forehead. Tension equal in both eyes, but rather more than normal; eserine continued. Next day all pain and feeling of heaviness gone; tension almost normal. In this case previous course of salines and A.P.C. was unavailing, as was complete withholding of A.P.C. while in hospital. Seven days later there was no recurrence of symptoms, and tension quite normal in both eyes. Fourteen days later disks showed cup 4 D in depth in each eye. Vessels seemed slightly tortuous. Otherwise normal.

DISCUSSION

If from lack of knowledge I am making too much of this, to me, new symptom-complex if it is because I can find no reference to anything of this sort in the ophthalmological textbooks at my disposal, nor have I read or heard of it elsewhere. The condition is unusual, in that primary rise of tension is associated with older persons, and the rise was not accompanied by the usual symptoms and signs of glaucoma, nor was the pain of the same type or distribution. Thus one would not readily associate this type of headache with an ocular lesion. It appears possible that many of the frontal headaches that are diagnosed as migraine in absence of vomiting and nausea may be due to this condition. Further, in view of Case 4, this condition should be borne in mind in all cases of frontal headache of obscure origin. It would seem that to have met four cases in four months in the relatively small community of Ambala suggests that this condition of increased intraocular tension may be a common cause of undiagnosed frontal headache. It would be gratifying and helpful to know whether eye specialists or others are familiar with a syndrome such as the one described.

MEDICAL, SURGICAL, OBSTETRICAL

CANCER OF THE HARD PALATE: TWO CASES

As two cases of cancer of the hard palate recently came to my notice, interest led me to search the literature I possessed which dealt with this subject. Such descriptions as I have found depart so far from my cases that I consider it may be useful to portray them.

Case 1.—A man, aged 65, and a heavy pipe smoker, had noticed seven years previously a small smooth swelling surmounted by a little white ulcer on his hard palate, adjacent to a necrosed second molar tooth. The only symptom which attracted his attention to the swelling was a sensation of itching, the irritation being increased by pressure. Some two years afterwards he noticed that the swelling had begun to spread, and about the same time he began to have occasional shooting pains to the ear on the same side of the head. This was diagnosed as neuralgia, for which he was treated. Three years later the tooth was removed, but the growth of the swelling was not arrested. Seven years after the onset he consulted his doctor. The Wassermann reaction was negative. A portion of the tumour was removed for microscopical examination, and the following report was obtained: "A carcinoma of basal-cell type, infiltrating the deeper tissues and showing ulceration."

On examination of the roof of the mouth prior to operation a slightly raised swelling was seen covering the posterior half of the hard palate, and extending slightly on to the soft palate. It involved the left alveolus up to the inner margin of the tooth bed, but did not extend on to the right alveolus. The surface of the swelling was somewhat redder in colour than the normal palate, but not markedly so. To the touch it was smooth, and of a varying rubbery consistence; it could not have been described as hard or nodular. Immediately

medial to where the necrotic tooth had been removed was a small ulcer with a grey, sloughy base. The circumferential wall of the ulcer was clean-cut, and pressure on the swelling in close relation to the ulcer caused a small quantity of blood-stained, sero-purulent material to exude. A similar small ulcer was present on the anterior surface of the swelling. There was no glandular involvement. The man looked very grey and ill.

Case 2.—A married woman, aged 62, had a swelling on the inner aspect of two necrotic upper incisor teeth. A few months after it appeared, as the swelling had enlarged, she sought advice. The teeth were extracted, and the blood taken gave a negative Wassermann reaction. A portion of the growth was removed, and the following report was obtained: "Histological examination of this specimen shows it to be a squamous-celled epithelioma deeply infiltrating the tissues."

The swelling in this case occupied the anterior third of the hard palate, and extended forward over the alveolus, but only where the two middle incisor teeth had been. The swelling was again smooth and of a rubbery consistence, and showed signs of a sinular ulceration. There was then no glandular involvement. The woman looked unduly ill for the size of the lesion.

The main points of interest in these two cases are: (1) the patients were 65 and 62 years of age; (2) both growths appeared to take origin in relation to necrotic teeth; (3) neither growth presented the hard, irregular, nodular appearance of textbook description. Both were smooth and rubbery in consistence, with clean-cut ulcers upon them; (4) the patients looked unduly ill, having regard to the extent of the lesions.

JOHN J. ROBB, M.C., M.B., F.R.C.S.,
Assistant Surgeon, Dundee Royal
Infirmary.

ON CLEANSING FOUL MOUTHS

The purpose of this note is to record a method of treating cases of generalized stomatitis which has been found useful in practice. It met with particular success in three cases which were marked by very foul mouths secondary to general systemic conditions. These cases were of pemphigus, purpura haemorrhagica, and agranulocytic angina. In the case of pemphigus the mouth and pharynx had become so ulcerated and foul, in spite of ordinary routine mouth toilet, that the patient was almost completely unable to swallow, and a gastrostomy was very seriously considered. The method about to be described cleaned up the mouth in a few days.

Every two hours when the patient is awake, and at least every four hours if asleep: (1) The mouth is thoroughly sprayed in every part of it with a 1 in 2,000 solution of peracaine in glycerin, about half an ounce to an ounce of the solution being used. This renders the mucous membrane sufficiently anaesthetic for the patient to tolerate vigorous swabbing. (2) Advantage is taken of the oral anaesthesia for the patient to be fed, and whatever form of liquid nourishment has been ordered is now given. (3) Every part of the mouth is thoroughly swabbed with a 50 per cent solution of hydrogen peroxide, and then re-swabbed again just as thoroughly with citric acid solution, 10 grains to an ounce of water. Soft swabs held in forceps should be used, and every corner of the mouth must be reached. (4) The mouth is irrigated with a pint of eusol solution, one part to three parts of water. The irrigation is carried out by means of a catheter attached to a douche can or by the use of a Higginson syringe.

The success of the method is dependent upon the peracaine anaesthesia permitting really thorough swabbing, and upon the use of three antiseptics one after the other instead of merely one. Incidentally, I have found eusol solution, 1 in 3 or 1 in 4, the most effective of all gargles for tonsillitis. It should be used hourly.

Reports of Societies

THERAPEUTICS AND PHARMACOLOGY

Therapeutic Action of Injectio Ferri

At the meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine, on January 9th, with Dr. J. H. BURN in the chair, a paper by Dr. L. J. WITTS and Mr. G. N. BURGER, on the therapeutic action of injectio ferri (B.P.), was read by the former.

Dr. Witts said that those of them who were interested in the treatment of anaemia were rather surprised when the injection of iron was introduced into the *British Pharmacopoeia*, 1932. The inclusion was made because there was a general feeling that injections of iron were useful; but general feelings of that kind were often erroneous, and, from what he had seen before, the reputation of injections of iron had been almost entirely based on the treatment of patients who would have got well without any treatment at all, or, in many cases, on the psychological effects of injections on patients with debility who were not really suffering from anaemia. The results of following up the treatment by injections of iron showed that the results were almost uniformly unsatisfactory. Until the last few years little was known about the effect of injections of iron. It had been concluded that iron was of no value at all when it was injected, and that it was only active when it entered the body by the alimentary tract or the portal circulation; but recent experiments left no doubt that anaemia in human beings could be cured by the injection of iron; such treatment, however, was found to be fraught with difficulty, because the therapeutic dose of iron by injection was so close to the toxic dose. It was not usually realized how toxic iron was by injection, although this had been established by animal experiments. The maximum official dose of injectio ferri (B.P.) was 2 c cm., which contained 7 mg. of metallic iron. He proceeded to show how these injections had been carefully tested in ten cases of anaemia. These were chronic and torpid cases, which showed no tendency to spontaneous recovery, and were unlikely to be influenced by uncontrollable factors. After an adequate control period injectio ferri (B.P.) was given intramuscularly daily for periods of from ten to twenty-one days. In no case were toxic symptoms observed. It was found to be of advantage to add 3 per cent. procaine hydrochloride to the injection of iron, as otherwise there might be local pain. After the experimental period of parenteral administration, oral administration was continued, usually 90 grains of iron and ammonium citrate.

Dr. Witts showed graphs and described in detail the history of eight of the ten patients to whom the official dose was given. All these patients subsequently responded well to large doses of iron by mouth, but two did not respond at all to the injection of iron. The iron was always more effective by mouth than by injection, as shown by the occurrence of a second reticulocyte crisis in every case, and there was also always an increase of haemoglobin. In only one instance was the increase in haemoglobin greater during the injection period than during the administration by mouth. He concluded by saying that hypochromic anaemia in human beings could sometimes be repaired by injection of iron, but this was much inferior to large doses of iron by mouth. Iron absorbed by the body in anaemia was converted, roughly quantitatively, into haemoglobin. It was not a mysterious stimulus to the bone marrow, but a raw material for haemoglobin manufacture. A calculation from the average values for the increase of haemoglobin during the injection period of iron in these cases showed that to cure anaemia of ordinary severity the maximal official dose of iron would have to be injected daily for four months. The only other way in which to approximate to as good an effect by injection would be to double the daily dose (as was done in two of the ten cases for a short period) for about six weeks. In the great majority of cases this

would be intolerable to the patient and fantastically expensive as compared with administration by mouth. One could only reiterate the opinion that the injection of iron was a very unsatisfactory form of treatment for anaemia, save in the most exceptional cases, and that the minute dose of iron so commonly given by weekly or bi-weekly injections was a very irrational form of treatment for anaemia, and one to be deplored.

The PRESIDENT said that he was one of those who were responsible for urging the inclusion of *injectio ferri* in the new *British Pharmacopoeia*, but the trouble was the absence of precise clinical observation. Dr. Witts had very clearly proved his case, and one might almost suggest that it looked as though, if they wanted to get precise clinical observations about any particular substance, they should put it in the *British Pharmacopoeia* first of all, and then people would be more interested to make careful observations concerning its use.

Toxic Effects of the Carbon Tetrachloride Group

Sir WILLIAM WILLCOX, at the same meeting, spoke on the toxic effects of substances of the carbon tetrachloride group. He said that these substances were coming into increasing use for many purposes commercially, and their toxic effects must not be disregarded. These effects varied according to the way in which the drug was administered, the time factor, and many other conditions. These carbon tetrachloride substances had been known for many years, and in old literature one discovered that many of them were employed for anaesthetic purposes and afterwards discarded. Carbon tetrachloride, for example, was introduced many years ago at about the same time as chloroform, and it was found to be inferior. All these drugs were anaesthetics. They had a toxic action on the brain, they were fat-soluble, were quickly absorbed, and produced narcotic effects. He had on several occasions called attention to the danger from liver poisoning of this group of drugs. The liver was the great protector against poisons. It was the organ which was usually the first to give up its life, so to speak, for the rest of the body. It had always occurred to him that the toxic effects of a drug really depended on the percentage in the blood at any particular instant, and that was specially so with a drug like chloroform. If there was 6 per cent. chloroform vapour in the air inhaled a few breaths might kill, whereas one might go on breathing 2 per cent. chloroform vapour for days perhaps without danger. In 1909 a young lady was having her hair shampooed at a London store when she fell back dead. Experiments showed that in the shampoo there was 4 or 5 per cent. carbon tetrachloride, and the inhalation of this would give a high percentage in the blood. The death was due to heart failure, the poison acting on the heart muscle. Recently he had had the opportunity of seeing at the Royal Naval Hospital at Chatham three cases under the care of Captain Dudley of patients who had been subjected to the vapour of carbon tetrachloride, which had been used for extinguishing fires on board ship, and in all of these cases, probably due to the way in which the vapour was inhaled, the blow of the poison fell, not—as he thought it would do—on the liver and brain, but on the kidney, and all of them showed marked impairment of renal function. One of the cases was the most remarkable of its kind that he had ever seen in his career, for there was complete suppression of urine for ten days, with, he was glad to say, thanks to the efforts of Captain Dudley, complete recovery.

Sir William Willcox then mentioned some related substances. Of the methane group there had been a good many cases of methyl chloride poisoning owing to leakage from refrigerators; the substance had a toxic action on the nervous system. Dichloromethane was given a few years ago as an anaesthetic, and there were several deaths from it. Chloroform, another member of this group, occasionally gave rise to toxic effects. As for carbon tetrachloride itself, it was employed very largely as a solvent for fats and resins, and, in medicine, it was

administered internally for ankylostomiasis. There had been a considerable number of deaths from toxic jaundice caused by this substance; even when death did not occur the liver might be damaged. It was also used for fire extinguishers, and its vapour was very toxic. Of the ethylene group, dichloroethylene was a toxic substance, but he had not met with cases of poisoning from it. Trichloroethylene was being employed commercially for removing fat and as a solvent; and here he mentioned a case under Dr. Reginald Miller of a boy of 16, employed at some electro-plating works, where his job was to dip razor blades into a solution. Before admission to hospital he had had jaundice for a month, he had a little albumin in the urine, and his liver was enlarged. Later the jaundice cleared up, the liver subsided, and the boy got better. On inquiry at the works it appeared that there had been several cases of illness, though not such deep jaundice. Of the ethane group, ethyl chloride was a volatile liquid given as a local and general anaesthetic—not a very toxic substance, but there had been fatalities owing to its action on the brain. Tetrachloroethane was used rarely now, but at one time, when it was largely employed for varnishing aeroplane wings, there was a great outbreak of toxic jaundice in the aeroplane factories. It was still being applied, though on a small scale, as a solvent of cellulose, and cases of jaundice were being reported. Avertin, the new anaesthetic, was quite obviously, from its composition, a liver poison and a drug which must be administered with care. It was a good basal anaesthetic, but toxic to the brain and liver, and therefore his advice to those who gave it for anaesthetic purposes was not to use it in such a dose as to give complete anaesthesia, but only amnesia, and to supplement it with a safe anaesthetic such as gas and oxygen.

Captain S. F. DUDLEY, R.N., gave some details of the Chatham cases to which Sir William Willcox had referred. The fire extinguisher cases were practically unique, but it was interesting that cases of carbon tetrachloride poisoning had occurred in the felt hat trade in Germany, where hats were dipped into a solution containing this substance, and this seemed to rule out the possibility which had been suggested that in the Chatham fire the trouble was due to decomposition products caused by heat. The first of the cases began with vomiting and gastric disturbance, and a few days later developed mild jaundice. At the end of ten days the patient suddenly went into epileptiform convulsions, with blood pressure 220 mm. Hg, and blood urea over 300 mg. per 100 c.cm. Oedema of the lungs developed, and it appeared inevitable that the man would die, but he made a most remarkable recovery. There was no significant change in the urine apart from a very mild albuminuria. He thought similar cases might arise in other conditions after the employment of a fire extinguisher, and be attributed to the effect of a stuffy garage or saloon car, nobody remembering the cylinder of extinguisher which was used a day or two previously. The patient, who was almost moribund, had had only five minutes' exposure to the vapour and had emptied only half a cylinder, while another man, who was taking turns with him in putting out the fire, and must have had the same exposure, complained of no subjective symptoms, though on examination he was found to have an increased blood urea and a transient albuminuria. Only the other day there was a fire in one of the electrical shops in the dockyard, and as water could not safely be used in an electrical fire thirty cylinders of fire extinguishers were employed, and fifteen men were exposed for various periods from five minutes to half an hour. This, however, was in a big, well-ventilated workshop, and on examination afterwards he found, except in one man with a slight trace of albuminuria, nothing abnormal. One man had nausea and vomiting, but this he attributed to the sickly fumes from burning electrical installations. There was no sign of kidney damage in any of these men. Cases of slight poisoning from extinguisher vapour were easy to miss, but he imagined there must be a good many cases about that were attributed erroneously to other causes.

Reviews

SCIENCE AND SOCIETY

Our reason for considering in a single review the two books now under notice is that the reflection reached at the end of the one is the basis and *raison d'être* of the other. Professor RAYMOND PEARL concludes his book, entitled *Constitution and Health*,¹ with the statement:

"There is a kind of moral necessity to go forward in the attempt to get a better understanding of the whole nature of man, lest he perish. The material, mechanized civilization he has evolved may easily become a monster to destroy him unless he learns better to comprehend, develop, and control his biological nature. It is beginning to be seen that inventions and discoveries that cannot be intelligently managed after they are made are likely to be a curse rather than a blessing. The fact is, there has been a sad lagging behind the advance of science on the part of the non-scientific world."

The professor of biology in the Johns Hopkins University is concerned primarily with the understanding of human nature, while Dr. FRANK TRINCA, basing the importance and value of his work on a realization of the same need, is concerned primarily with economics in his book entitled *Science and Democracy*.² Until quite recently, and even now, except to a very limited extent, it has not been customary in orthodox works on economics to consider how far an understanding of the human element may modify its dry and abstract conclusions; so that, beyond the motive of setting forth the application of scientific knowledge in their respective spheres, a further link between the two volumes may be found in the necessary relationship of the one sphere to the other. Dr. Trinca strikingly quotes Professor William McDougall as saying:

"When conditions are bad, men are without work, children short of food, the malady from which society is suffering is plain ignorance of how to manage affairs of economics by knowledge of laws of life. In order to restore the balance of civilization, in order to adjust our social, economic, and political life to the violent changes which physical science has directly and indirectly produced, we need to have far more knowledge of human nature and of the life of society than we yet have."

Otherwise the two books are of a very different character.

Professor Pearl's little work—one of the *Psyche Miniatures*—is extremely interesting. Though not formally so divided, it really consists of three sections. In the first is considered the different approach of the biologist and of the ordinary medical man to the subject of human disease. It is put thus:

"The biologist who interests himself in pathology looks primarily upon disease as merely one part of the general biology of the organism. He thinks of it first as an interesting aberration from the usual normal functioning of the whole organism rather than as a specific, discrete, inimical entity, fastening on its victim. Medical men in the practical conduct of their business commonly tend to think of a disease as 'attacking' a man. The physician's function is often described as 'combating' or 'preventing' it . . . The biologist's way of looking at the matter is in sharp contrast to this: for him the alteration of the biology of the organism is the disease."

This passage is very apt just now, when it is becoming more and more important that a biological training should be made the foundation of that of a medical practitioner, and that the biological point of view should be ingrained in his thought and study. In the second section the author is concerned with the proper use and exact connotation of the word "constitution" as applied to

human beings. One usage implies that, at any given time, an individual's constitution is what he is, the totality of the particular individual being biologically considered, without immediate concern as to how it came to be what it is. Another usage implies that "constitution is *genetic* constitution *et præterea nihil*, determined solely by entailed ancestral genes, and therefore irrevocably fixed and without possibility of change except by gene mutations or accidents of meiosis." There is unfortunately a third use of the word by some writers to which Professor Pearl does not refer, meaning the bodily make-up at the moment of birth. This is, of course, merely a particular application of the first concept to a special moment, and should not imply anything as to how it came to be what it then was; but, unfortunately again, some of the writers thus using the word seem to assume that all the elements making up the "constitution" are of hereditary origin, an essential fallacy with serious consequences. It is important to be quite clear in any discussion as to which of these senses should be attached to the word. Professor Pearl would seem to wish it to be confined to the first connotation, but surely the second may be legitimate and useful if definitely understood. The author's discussion is illuminating, and incidentally he gives a somewhat fresh presentation of the meaning of "heredity" and "environment." In the third section Professor Pearl records the results of an investigation into the susceptibility to disease of human beings of different constitutions—the asthenic (tall and slim), the pyknic (thick-set), the euplastic (symmetrical), the dysplastic (asymmetrical). These are, of course, cross classifications as to bodily habitus, both asthenic and pyknic types being euplastic. In view of the importance—an altogether undue importance, as many think—which has been recently attached by some physicians and psychologists to these types, the results of the author's investigations are valuable. The conclusions are that:

"None of the differences in respect of health in the several bodily habitus types can be regarded as significant. They are not greater than might be expected to arise in random sampling. There is no sensible difference in general health between asthenics, pyknics, or intermediates taken as classes. . . . A careful statistical examination of rather accurate, if not very extensive, material does not yield evidence of any very marked or striking association between bodily habitus and general health."

Dr. Trinca's book is much longer and more laboriously constructed. It cannot be said to be so scientifically based, and it is adorned by a large number of remarkable split infinitives. It embodies, however, the exposition of a suggestion of fundamental importance with regard to the relations of scientific discovery, industrial expansion, and economic prosperity or depression. Dr. Trinca holds that, while it is the relationship between industry and finance which has hitherto almost exclusively engaged economic thought, the relation between science and industry is of far greater fundamental importance, and that this, if properly understood, will solve many of the difficulties with which the world is now faced and which the professed economists have so far acknowledged to be very incompletely solvable by them. The main fact is that, while there may be an almost continuous movement of minor scientific adaptation and improvement, the basic discoveries resulting in major industrial progress are by no means continuous, as most economists have assumed, but occur only as epochs; and that even when this matter has been perceived by economists its importance and its consequences have not been given the weight which should be attached to them. Dr. Trinca works out his thesis with great care and precision. But it is not every reader who will be able to accompany him so appreciatively through his later chapters.

GENERAL EFFECTS OF CHRONIC NASAL
SINUSITIS

A second edition of *Chronic Nasal Sinusitis and its Relation to Medicine*,² by PATRICK WATSON-WILLIAMS, has been found necessary in a short space of time after the publication of the first edition. The scope of this book is wider than the title might lead the reader to expect, for although the part played by the accessory sinuses is the chief consideration, the work is really an account of the relation of focal sepsis to general medicine. Dr. Watson-Williams has been known for some years as an advocate of examination of the accessory sinuses, especially the sphenoidal, in certain cases of insanity, and he here gives a detailed account of his views on the relation between focal sepsis and pathological states of the nervous system. He has added some further interesting observations in the present edition. The illustrations also have been amplified, in particular by some drawings made by the author himself of the views obtained by nasal endoscopy.

The importance of this aspect of general medicine has now been established for many years, but its importance is no greater than the difficulties and contradictions with which its application is beset. Dr. Watson-Williams does not neglect to indicate the caution required, and warns against an obsession which may cause diabetes or a malignant neoplasm to be overlooked. Although a portion of the book is devoted to rhinological technique, much of which the author has himself devised, the greater part must be of profound interest to the general physician and of help in the elucidation of many obscure maladies.

NEUROPATHOLOGY

Two new books on neuropathology have reached us from Chicago. In the *Histopathology of the Peripheral and Central Nervous Systems*,⁴ Professor HASSIN has drained a rich store of experience and observation. How wide a field is covered is shown by the chapter headings, which include more than one hundred and fifty different morbid conditions of the nervous system. The descriptions of most of these, while not exhaustive, are at least adequate to the needs of the average reader, and they are supplemented by a profuse hithography and good photomicrographs. The author's training in the German school of neuropathology is everywhere evident. Indeed, his frequent use of German descriptive words may be confusing to those unfamiliar with the subject, and he does not always seem to have corrected his earlier learning in the light of more recent discoveries by the Spanish neurologists. He is apt also to take for granted more knowledge of the normal histology of the nervous system than is usually possessed by neurologists, as he has been obliged by considerations of space to omit any general description of neurons and neuroglia cells, and of their alterations in disease. While in most respects the book follows conservative lines, the author's unconventional views of the pathogenesis of some diseases, such as tabes dorsalis and hydrocephalus, give it a spice of originality. The last thirty pages, on staining methods used in neuropathology, are a valuable addition to the book.

Dr. WEIL's *Textbook of Neuropathology*³ may be said to fill the gaps left by Professor Hassin. Here the reader will find clear statements of the chemical structure and

metabolism of nervous tissue, as well as of its cellular structure, and of the changes to which its various cell types are liable in disease. The discussion of the effects of post-mortem autolysis and fixation on the brain is valuable and suggestive, and the description of post-mortem technique will be helpful to many. There are excellent chapters on inflammation and the effects of toxins, and the survey of tumours of the nervous system is remarkably complete. From it we learn that tumours of the brain are the cause of death in from 1.5 to 2 per cent. of the population. These figures, which are taken from German sources, and go back as far as the year 1854, are in remarkable agreement with those which have just been published from the Leeds General Infirmary by Garland and Armitage, and which cover the years 1910-31. Throughout the book full use is made of tables, which convey much valuable information at a glance. Indeed, the author has everywhere succeeded in presenting his subject in a concise and yet easily assimilable form. In this he is helped by the numerous excellent illustrations. In many respects it is a book which breaks new ground, and which should therefore be valuable not only to the beginner, but also to those who already possess considerable knowledge of the subject.

RESULTS OF ARTHRODESIS OF THE HIP

Dr. PAUL BUFNOIR was for some years house-surgeon at the Maritime Hospital at Berck-sur-Mer, of which at that time Professor E. Sorrel, now of Paris, was the director. Dr. Bufnoir has since made a study⁵ of late results of operations for the fixation of affected hips in cases of coxalgia to which Professor Sorrel contributes a valuable preface. It is important to ascertain to what extent the apparent good results of arthrodesis, at the time of discharge from hospital, are maintained in the course of years. The facts ascertained by Dr. Bufnoir on this subject should be of considerable value to surgeons anxious to know which method gives the best prospect of permanent relief. He has followed up one hundred cases which were discharged in excellent condition, of which he succeeded in tracing seventy-five, who long after discharge have continued to carry on their occupations and live a normal life. These seventy-five cases have furnished indications from which to judge the value of the different proceedings employed.

In the first part of the work Dr. Bufnoir discusses the arthrodeses effected in cases of active disease (generally in adults), but rarely in children (eight old-standing cases), and concludes that in adults arthrodesis improves the prognosis in hip disease in selected cases. It appears to him that the best method is the para-articular with rigid tibial bone graft after Albee's method. These late results were better than had been expected, and, according to Professor Sorrel, this operation, still rather new (for plenty of arthrodeses for the sequelae of hip disease have been performed, but very few in active disease), deserves to be better known and more often practised than it is at present. In children, on the other hand, arthrodesis seems usually inapplicable, and, except in chronic cases, it should not be done (Sorrel).

In the second part of his book Dr. Bufnoir discusses arthrodesis for the sequelae of hip disease. He quotes thirty-eight old-standing cases, and comes to the following conclusions: Arthrodesis of the hip is a very good operation in cases in which the joint remains movable but painful, with a tendency to a vicious position; there are numerous techniques available; simple intra-articular arthrodesis is generally inadequate and should be abandoned; juxta-articular arthrodesis of the Mathieu-

² *Chronic Nasal Sinusitis and its Relation to General Medicine*. By P. Watson-Williams, M.D. Second edition. Foreword by Sir Humphry Rolleston, Bart, M.D. Bristol: J. Wright and Sons, Ltd. 1933. (Pp. 262; 122 figures. 15s. net.)

⁴ *Histopathology of the Peripheral and Central Nervous Systems*. By George B. Hassin, M.D. London: Baillière, Tindall and Cox. 1933. (Pp. 481; 227 figures. 36s.)

³ *A Textbook of Neuropathology*. By Arthur Weil, M.D. London: H. Kimpton. 1934. (Pp. 335; 260 engravings. 25s. net.)

⁵ *Les Arthrodeses dans la Coxalgie*. Par Paul Bufnoir. Paris: Masson et Cie. 1933. (Pp. 110. 29 fr.)

Willmott type gives excellent results, and better still when combined with an intra-articular method. In a final special chapter the author indicates the troubles which may arise from the opening of foci of active disease in the course of operations; whenever this happened in cases of active hip disease the results were bad. In cases of the sequelae of hip disease, however, the opening of an old focus, not quite extinct but of little virulence, is of no consequence.

This book is illustrated with reproductions of radiographs and case reports, and should be useful to surgeons. No indication is given, however, of the precise pathology of the various lesions discussed. It is to be presumed, however, that at Berck-sur-Mer most of the cases were tuberculous.

THE POCKET ANATOMY

A good rule in learning anatomy is to follow the advice we once heard one student give another—that of looking up any doubtful point at once. With dissections and lectures over, and the examinations approaching, the average student will often have occasion to refer to a book in this way, and the *Pocket Anatomy*¹ has for many years been a favourite for this purpose. The compression which has enabled the main facts of anatomy to be presented in 300 small pages, and the absence of illustrations, make the volume unsuitable as a textbook. Its usefulness lies in the fact that it really will go into the pocket; and, owing to the arrangement under systems, the plan of lettering and bracketing adopted, and the provision of an excellent index, facts can be verified with the minimum of effort. The student will find it necessary to consult the larger textbooks for the more accurate detail. The statement that the posterior thoracic nerve pierces the scalenus medius muscle is not strictly true. A description of the pancreas is given without any mention, for example, of the accessory duct. Such brevities are unavoidable in a book of this size, though they may fail to satisfy the more academically minded. The new edition differs from its long line of predecessors in the change to the nomenclature recently adopted by the British Anatomical Society; here the glossary given at pages 303–306, containing the old equivalents of the new terms, will be found of great value. Another change is in the section on the nervous system, which has been brought up to date by the inclusion of additional matter on the autonomic nervous system. There is no doubt that in its new form the familiar *Pocket Anatomy* will continue to enjoy the popularity it has had for so many years.

Notes on Books

The second decennial *General Index to the British Journal of Surgery*² relates to vols. xi to xx, and covers the period from July, 1923, to April, 1933. In the preface Sir D'ARCY POWER points out that its appearance marks a further stage in the progress of British surgery, for, whereas its predecessor revealed the then domination of war surgery, the present volume is mainly concerned with civil work, attention being devoted more especially to the surgery of the nervous system, the alimentary canal, the liver, and the ductless glands. With advancing knowledge and new achievements a new nomenclature is necessarily being created, and Sir D'Arcy Power remarks that the multiplication of terms will soon call for the compilation of an explanatory dictionary! Book reviews appear in two lists: under their titles and under the names of the authors. The index will unquestionably be of great assistance to those who wish to trace references to topics in any of the widening fields of modern surgery.

¹ *The Pocket Anatomy*. By C. H. Fagge, F.R.C.S. Ninth edition. London: Baillière, Tindall and Cox, 1933. (Pp. 333, 8s.)

² *The British Journal of Surgery. General Index 1923–1933*. Numbers 41–80. London: Simpkin Marshall, Ltd. 1933. (16s. 6d. net.)

We have received a copy of the August, 1933, issue of *Archivos de Medicina legal e Identificação*,³ the official organ of the Brazilian police. The work contains original articles and lectures on criminal anthropology, new methods of medico-legal laboratory technique, instruction in medical jurisprudence in Brazil during the last hundred years, the detection of mental diseases in prisons, legislation on the insane, the penitentiary of São Paulo, sterilization of the unfit, the psycho-analytic conception of punishment, women in the prevention of crime, and records of cases of medico-legal interest, news, and reviews. This publication will be sent gratuitously to scientific institutions or medico-legal specialists on request made to the director, Leonarido Ribeiro, 84, Rua do Lavradio, Rio de Janeiro, Brazil.

The second edition has now been issued of *The Conjoint Finals*,⁴ a reproduction of all the questions set in medicine, surgery, and midwifery from 1911 to 1932 at the English Conjoint Board examinations. These are classified under the various systems and arranged in the chronological order of their setting. A new section has been added to this edition relating to pathology and bacteriology. Such a compilation will no doubt be welcomed by the medical student approaching his final examinations.

The Imperial Bureau of Animal Health has compiled a list of publications relating to animal health and disease under the title of *Index Veterinarius*,⁵ the first volume being dated April, 1933. The book has been produced by a duplicator, but the text is easily readable, and careful designing has ensured that any particular reference can be traced quickly. One section is devoted to abbreviations of the names of publications. This is followed by a classified alphabetical author-index and subject-index of signed articles, and a classified subject-index of anonymous articles. This arrangement should prove satisfactory in general use, especially as care has been taken to provide full cross-references, and instructions at the beginning of the volume show how to proceed in any particular inquiry. So painstaking an effort should need no special commendation to those concerned with diseases of animals who desire information about the literature relating to the subject.

³ *Archivos de Medicina legal e Identificação*. Rio de Janeiro: Imprensa Nacional 1933. (Pp. 302.)

⁴ *The Conjoint Finals*. By G. N. Beeston, M.R.C.S., L.R.C.P. Second edition. London: John Bale, Sons and Danielsson, Ltd. 1933. (Pp. 138, 6s. net.)

⁵ *Index Veterinarius*. Vol. i. No 1. 1933. Weybridge, Surrey: Imperial Bureau of Animal Health. (Pp. 303. Annual subscription, £4.)

New Preparations

DEKRYSL

Dekrysil (Crookes Laboratories) is a preparation of 4:6 dinitro-o-cresol. Attention was drawn to the powerful action possessed by dinitrophenol of raising basal metabolism by work in Heymann's laboratory in 1928, and the clinical application of this action has been investigated (Tainter et al., *Journ. Amer. Med. Assoc.*, 1933, ci, 1472). Dodds and Robertson (*Lancet*, 1933, ii, 1137, 1197) investigated dinitro-o-cresol, and found it to be approximately five times as active as dinitrophenol. The relation of these drugs to trinitrophenol has naturally suggested the possibility of their producing injury to the liver, but little direct evidence of this has been obtained.

Dodds and Robertson found that dinitro-o-cresol was extremely potent in raising basal metabolism, and suggested a dosage of from 0.5 to 1 mg. per kilo of body weight. They observed that the drug caused reduction in body weight but unfortunately did not produce any general relief of the symptoms of myxoedema. It is therefore suitable for the treatment of obesity, but does not relieve thyroid hypofunction. These authors found that toxic symptoms occurred when the basal metabolism was raised more than 50 per cent.

Dekrysil is put up in capsules containing 50 mg., and the makers wisely stress the fact that it is an extremely potent remedy, to be used with caution and respect. Dekrysil is obviously a very powerful drug with an extremely interesting pharmacological action. The manufacturers have taken the wise precaution of marking their bottles "To be administered only on medical prescription."

British Medical Journal

SATURDAY, JANUARY 20th, 1934

LONDON COUNCIL HOSPITAL SERVICES

Now that more than three years have elapsed since the "appointed day" under the Local Government Act, 1923, on which the hospital and allied medical services were transferred to the London County Council, the Central Public Health Committee of that body has prepared an account of the administrative progress made in the direction of co-ordination and satisfactory establishment of the services in question. The London County Council has now under its management seventy-four hospitals, in which all types of cases are treated. The annual cost of maintenance is not far short of four and a half million pounds, and the staff approaches a total of 18,500. The committee realizes that it is too soon to claim that the task of building up a satisfactory municipal hospital service for London on the basis of services formerly provided by twenty-six separate authorities is within sight of completion or is likely to be achieved for some years; but the transition from diversified control to central direction has taken place smoothly and successfully, and, administratively, the services have been placed on a basis which renders possible sound development in the future.

One new convalescent hospital of 500 beds (at Sidcup) has been acquired, and another of 320 beds (at Tooting) reopened. At about thirty hospitals major schemes of extension and enlargement have been carried out. Accommodation for maternity cases has been extended by 112 additional beds, and arrangements have been made for ante-natal attendances at all the general hospitals at which there are maternity wards. A comprehensive modern pathological laboratory service has been made available for all hospitals, and a consultant and specialist service has been established. The district medical service has been reorganized, subject to further review in two years' time, and greater use is being made of the voluntary district nursing services in London. The total bed accommodation in the hospitals and allocated institutions on transfer was 41,164, but this included 9,620 beds in institutions, the majority of which could not be regarded as suitable for the proper treatment of sick persons. When certain well-advanced structural works are completed the accommodation in the hospitals will show a net increase during the three years of more than 1,400 beds. There is an increasing demand on the Council's maternity accommodation. During 1932 more than one-sixth of the births in London occurred in the Council's institutions. Special arrangements have been made for women suffering from puerperal fever, and out of nearly 11,000 cases confined in the hospitals in 1932 there were only twelve deaths from puerperal infection. The ante-natal clinics were attended in 1932 by 9,448 expectant mothers, who made 48,618 attendances.

At very few of the general hospitals had the late boards of guardians granted facilities for medical education or research. Arrangements have now been made to afford facilities for clinical demonstrations to undergraduate and post-graduate students at a number of the Council's hospitals and to associate for the purpose each teaching hospital in London with one or more of the municipal institutions. This includes teaching in obstetrics at two of the Council's hospitals, and it is gratifying to learn that the facilities for this teaching will in course of time be extended to all the medical schools. Facilities are also afforded at the Council's pathological laboratories to post-graduate students in order that they may obtain experience in technical and administrative methods. Here we may recall that the British Post-Graduate Hospital and Medical School, in association with the Council's hospital at Hammersmith, will be ready for opening about November, 1934.

With regard to the medical staff, numbering about 300, it is mentioned in the Central Public Health Committee's report that scales and conditions have been approved and establishments fixed. A complete consultant and specialist service in all necessary branches has been organized on a sessional basis at groups of hospitals, and it is considered that a part-time consultant service is better than a whole-time service, but provision is made for the apportionment of the services of whole-time consultants when this is considered advisable. More than 200 appointments of part-time consultants have been made. "The Council's scales of remuneration approximate to those of the British Medical Association, except in the case of anaesthetists, where the existing scale for anaesthetists employed in the school medical service was taken. In selecting consultants and specialists to fill the positions the Council had the valuable assistance of many eminent members of the medical profession." The Council's female nursing staff, for which scales and conditions have also been approved, numbers about 9,000. It is added that since the transfer in 1930 meetings have taken place on five occasions between representatives of the London Voluntary Hospitals Committee set up for the purpose of consultations under Section 13 of the Local Government Act, 1929, and the Council's representatives, when matters of mutual interest have been discussed. More frequent conferences of this kind would be all to the good.

CONCERNING ATELECTASIS

American medical literature is full of references to the subject of atelectasis; we in England have not taken kindly to this name, preferring the description lobular, lobar, and massive collapse for the acquired forms and retaining "atelectasis" for those of congenital origin. Massive collapse occurring after operations on the thyroid, abdomen, and buttocks is by now a familiar condition, which Briscoe has ascribed in part to contraction of the crural portion of the diaphragm, leading to deflation of the lower lobe. This occurs in conditions of debility or toxæmia, and local inflammation or pleurisy may initiate or increase the process. With

regard to the less dramatic event in which smaller portions of the lung collapse we are only beginning to recognize and separate it from a welter of other conditions, such as chronic pneumonia, fibrosis, and the like. It is probably commoner in chronic pulmonary tuberculosis than has hitherto been thought, and it is likely to be the explanation of those sudden cures and alterations of extensive x-ray shadows for which an explanation has previously gone begging. But Rosenblatt¹ quotes a case following haemoptysis in which the severity of the condition was probably increased by the administration of large doses of morphine. This author follows ordinary opinion in reviewing possible factors, such as a plug of tenacious sputum and bronchial stenosis due to a lesion round the bronchus (in this case the collapse is likely to be permanent), concluding that it is reasonable to assume that in this patient the atelectasis was caused by a blood clot retained in a bronchus and plugging it for a sufficient length of time to allow the residual air to absorb and the lung to collapse. Ehrenburg² browses over the whole subject in a rather inconsequent way, but does produce evidence that this explanation is not borne out by the experimental work reported in the literature. In animals it is only with great difficulty that a bronchus can be blocked, since the threefold mechanism of cough, peristalsis of the bronchial muscle, and ciliary action forms a very effective protective contrivance. In particular the work of Van Allen and of Lee shows that it is usual to fail to produce atelectasis in dogs with all the more obvious methods. In man blood-stains have been observed, through the bronchoscope, to travel from the carina to the larynx in a few minutes in patients under general anaesthesia.

Experimental evidence goes to show that the usual theory that collapse is due to occlusion of a bronchus by mucus, inflammatory matter, or caseous masses may be incorrect. Two explanations remain: the first is that there is reflex contraction of the sphincter muscle of the respiratory bronchiole described by Miller; the second, which is Ehrenburg's own view, appears to be a development of the observation that at rest many alveoli are collapsed. We yawn or take a deep breath on waking up; we advise patients suffering from prolonged illnesses to shift their position to make them cough or breathe deeply. In the atelectasis of pulmonary tuberculosis there is, he says, "atrophy from inactivity of the lung parenchyma followed in long-standing cases by hyperplasia of the connective tissue." The difficulty of distinguishing, in the x-ray film, fibrosis from pulmonary collapse lies largely in the varying density of the shadow cast by the collapsed area. This depends entirely upon the degree of vascularization, as shown in observations during collapse therapy. Ehrenburg quotes the experiments of Andrews, who proved that the gradually collapsed lung continues for the first eight days to transmit 30 per cent. of the calculated cardiac output. Since the collapsed lung gradually becomes fibrotic its blood supply diminishes, and thirty

days later it transmits only 8 per cent. Of obvious assistance in diagnosis are the displacements of the mediastinum and the rise with peaking of the diaphragm on the corresponding side. Sometimes the condition can only be recognized by the sudden alteration in a subsequent x-ray photograph in which the shadow has apparently cleared. In Ehrenburg's second case the patient was suffering from urticaria at the time of his attack of lobar collapse, and as this could not be relieved by strict dietetic measures "it was evidently an allergic reaction to his bronchial secretion. Such an allergic reaction might occur during his relapse and might be responsible for the spasm of the bronchial muscles with occlusion of a middle-sized bronchus." The reasoning here is hardly convincing, and many observations will be necessary before this particular line of explanation will be generally adopted.

Various problems in connexion with the so-called pulmonary atelectasis in the newborn have never been altogether satisfactorily solved, and yet the subject is of great practical importance if a big group of cases of respiratory failure at this age is to receive proper treatment. In a recent valuable review³ of the disorder Drs. S. Farber and J. L. Wilson survey the somewhat controversial literature dealing with the problem, and produce useful new evidence of their own findings. One difficulty in investigating the subject has always been the histological similarity between a lung that has never expanded and a lung in which inadequate or enfeebled respiration has led to a secondary "resorption" of air and subsequent collapse. Some workers have expressed the view that all atelectasis in the newborn is of the latter type, but the present authors, from observations on human subjects and from experimental evidence, point out that once expansion of an alveolus has occurred the lining cells lose their foetal cuboidal shape, become flattened, and never again return to the original appearance. They further point out that the expansion of the lungs is not a sudden process, accomplished by the first breath, but that, even in the full-term infant who breathes well and suffers from no obvious interference with respiration, from two to four days are normally required for complete expansion of all portions of both lungs, microscopically as well as grossly. In the case of the premature infant a period of six weeks or longer may be required. It follows that the finding of a certain amount of unexpanded pulmonary tissue at necropsy in an infant dying in the first few days of life is to be regarded as a normal condition, and cannot be accepted in itself as a cause of death in the newborn. A further difficulty arises in premature infants, for solid areas of parenchyma superficially resembling atelectasis may be found which, on detailed study, according to the present workers, actually represent portions of incompletely developed pulmonary tissue which are quite incapable of expansion. In a further study⁴ Farber and Wilson attack the problem of the pathogenesis of atelectasis in the newborn. Asserting that the "resorption" type of

¹ *Brit. Rev. C. Tuberculosis*, xxviii, August, 1933.
² *Ibid.*, xxviii, xxi, 1933.

³ *Amer. Jour. Dis. Child.*, 1933, xlii, 572.
⁴ *Ibid.*, 1933, xlii, 599.

atelectasis must be secondary, they proceed to analyse the causation of the primary type of collapse, believing that even in such cases there must be some primary cause preventing the expansion of normally developed lung. By measurement of the resistance to expansion of the lungs of dead infants and of dead and living animals they show that cohesion of the moist surfaces of the air passages in collapsed and airless lungs offers a considerable obstacle to the entrance of air, and that a relatively great force is required to separate the bronchial and alveolar walls during the initial expansion. The first breath of a newborn baby may thus be a most difficult one, and for a variable period after birth especially vigorous inspirations must be maintained. Other factors are often present besides this cohesion. For example, an imperfectly developed or damaged respiratory centre may fail to bring about vigorous enough respiratory movements; or an imperfectly developed thoracic mechanism, as is seen in premature infants, may fail to provide a satisfactory bellows action in conjunction with the diaphragm. Lastly, for practical purposes, and in the absence of conclusive proof to the contrary, we must agree to the possibility that bronchial obstruction due to the inspiration of the contents of the amniotic sac, mucus, or blood may cause extensive atelectasis, especially in full-term infants. There are many practical points for treatment arising out of the two papers here summarized: among others are the importance of clearing out the airways of the newborn infant, and the prompt use of carbon dioxide and oxygen mixtures (5 or 7 per cent. of the former) to promote big respiratory movements.

RADIUM IN OPHTHALMOLOGY

Of recent years a considerable amount of work has been done upon the general uses of radium in almost every department of medicine, and for a time it seemed that in ophthalmology much less progress was being made than in other branches. One of the reasons for this has been that, so far as the eye was concerned, radiation applied in any massive dose tends to cause a considerable immediate reaction in the eye and induces unfortunate sequels, such as the development of a radiation cataract. Largely owing to the ingenuity of Mr. Foster Moore, however, it now seems to be practicable to treat intraocular malignant tumours by the technique of inserting radon seeds into the eye; and, although the method has been applied to a few cases only, and the results in these are relatively recent and can show no long after-histories, the method seems to hold out considerable promise of usefulness. It must be insisted at the start that in no case is the new treatment by radiation as safe as excision, and that radical surgical procedures are by no means superseded; but it does occasionally happen that a sarcoma occurs in an only eye or in an eye whose fellow has no useful vision, and in infancy it happens too frequently that a glioma occurs in both eyes. In each of these cases, especially in the latter, radical treatment by the excision of both eyes is a very grave and distasteful course, and any alternative which does not involve frank

danger to life ought to be carefully considered. An extremely full and informative account of this recent advance in radiational treatment in ophthalmology has been written in monograph form by Mr. H. B. Stallard.¹ He himself has worked with Foster Moore, and speaks with first-hand knowledge of the technique of the insertion of a radon seed into the eye and the subsequent removal of the seed. So far as the technique is concerned the monograph itself should be consulted; but, although the cases reported are few, it can be safely deduced that gliomata of the retina and sarcoma of the uveal tract are radio-sensitive, and that the cells are destroyed by radium emanations, the zone of destruction varying with the strength of the seed. By far the best method seems to be the intraocular insertion of the seed, for it has been found that the application of the seed to the sclera by suturing is much less, if at all, effective, and is likely to produce considerable injury to the eye. The treatment of intraocular neoplasms constitutes much the most valuable part of the monograph, but there remain several other points of interest. Angiomatosis retinae (Lindau's disease) responded well to the superficial application of radon seeds to the sclera. With reference to the epibulbar tumours, it is recommended as the ideal method of treatment that excision by the diathermy knife should be followed by the application of radium to the affected site. Similarly, for a small localized rodent ulcer still movable over the deeper tissue radium is the treatment of choice; on the other hand, while the warty type of squamous-celled carcinoma of the lids responds well, the ulcerative form of the disease is resistant to radiotherapy. Another ocular affection in which good results are obtained is haemangioma of the lids and conjunctiva. With regard to the more chronic types of conjunctivitis, such as trachoma, vernal catarrh, pemphigus, and so on, the results reported in the literature are varied, and it seems probable that the conclusion reached in the monograph—that the treatment is unjustified considering the risks involved—is sound.

THE PITUITARY GLAND AND THE ACTION OF INSULIN

Recent work on the relation between the glands which appear to be mainly responsible for the control of carbohydrate metabolism has brought to light facts which complicate the problem to a very considerable extent. No simple or even approximately complete statement can be made of the complexities of carbohydrate metabolism. From a great mass of experimental evidence the conception of gluconeogenesis (endogenous formation of sugar) has been clearly justified, and the generally accepted view as to the group of disturbances in metabolism which is called diabetes is that this process of gluconeogenesis is exaggerated and to a greater or less extent out of control. In the early days of research into the action of insulin it was considered that this hormone was responsible for keeping gluconeogenesis within bounds, and when Dale and his co-workers demonstrated that insulin produces a great increase in carbohydrate oxidation and glycogen formation in the decapitated eviscerated perfused cat it

¹ Brit. Journ. Ophthalmol., Monograph Supplement vi, 1933.

seemed that the main features of the problem were clarified. The loss in weight, the ketosis, and the negative nitrogen balance in diabetes were all regarded as manifestations of an increased gluconeogenesis. In the diabetic patient or animal insulin restored the depleted glycogen reserves, restored the normal oxidation of carbohydrate, and led to the proper control of gluconeogenesis. In the meantime, Houssay and his collaborators in the Argentine had made the important observation that if the pituitary gland is removed from a dog after the pancreas had been removed then the principal signs of diabetes disappeared—that is, excessive gluconeogenesis was not in evidence. In such an animal without pancreas and pituitary the injection of certain extracts of the anterior lobe of the pituitary led to the establishment of a condition almost indistinguishable from diabetes. These workers naturally concluded that the processes of gluconeogenesis are under the control of the pituitary (anterior lobe). They also found that hypophysectomized dogs exhibited a very greatly increased sensitivity to insulin. In a recent contribution, Corkill, Marks, and White¹ have shown that the hypophysectomized rabbit tended to develop spontaneous hypoglycaemia, and was very sensitive to small doses of insulin. This hypersensitivity was observed even when the glycogen depots were well supplied by injection of glucose, and even severe insulin convulsions did not lead to removal of the liver glycogen. These workers also found that hypophysectomized animals developed a greatly increased glucose tolerance (cf. hypopituitary obesity) and that their liver glycogen was not readily mobilized by adrenaline or vasopressin, normally or during insulin hypoglycaemia. The tentative conclusion is drawn that the insulin hypersensitivity in the hypophysectomized animal is due to stabilization of the hepatic glycogen, which may be due to the secondary involvements of the thyroid or adrenal cortex which are known to result from the removal of the pituitary. No more can be said at this stage than that our conception of diabetes must be modified to include most of the endocrine glands, and that the pituitary gland has now to be considered as a fundamental factor in this disease.

ANTIMENINGOCOCCAL SERUM IN CEREBRO-SPINAL FEVER

A considerable number of individual records of cases of cerebro-spinal fever treated with antimeningococcus serum have now been collected at the Ministry of Health in consequence of the request addressed by the Ministry to medical officers of health, hospital medical officers, and medical practitioners, to which publicity was given in the medical press in January of last year. The request was made in order to obtain material to assess, in terms of case mortality and clinical course, the results obtained from the use of the several antimeningococcus sera employed in this country at the present time. It was based on a memorandum (*Administration of Antimeningococcus Serum in Cases of Cerebro-spinal Fever*, Ministry of Health, March, 1932) in which stress was laid upon the importance of the following considerations in serum treatment: (1) As soon as the

patient is suspected on clinical grounds to be suffering from cerebro-spinal fever, lumbar puncture should be performed; serum should be injected intrathecally without waiting for bacteriological confirmation. (2) The intrathecal doses given should ordinarily be in the region of 30 c.cm. (concentrated serum 10 c.cm.). (3) The injection should be repeated every twenty-four hours over at least three or four days or until convalescence is obviously established. The Ministry, in a statement issued last week, informs us that particulars have now been received of 811 cases treated in this way. Although this number is insufficient to justify a final conclusion, nevertheless, in view of the doubts sometimes expressed as to the utility of any kind of antimeningococcal serum, it is noteworthy that the case mortality in the 811 serum-treated cases is relatively low—26.9 per cent. at all ages—and to this extent is encouraging. The Ministry desires that it should be made known that the inquiry is still proceeding, and it is hoped that the medical officers and practitioners concerned will continue to aid the Department by completing the record forms which are sent out in respect of notified cases of this disease. It is only by the collection of sufficient numbers of cases in which serum treatment has been given on the lines above indicated that any satisfactory assessment of the effect of different sera can be made.

TREATMENT OF GASTRO-DUODENAL HAEMORRHAGE

The tendency to conservative methods in the treatment of severe gastro-duodenal haemorrhage has been based on the consideration that the immediate mortality from this complication is less than that which might be expected to follow radical surgical procedures undertaken at an unfavourable time, and the operative results would appear generally to support this view. On the other hand, it is urged that this high operative mortality necessarily follows the common practice of submitting patients to operation only as a last resort, and that on the basis of such results it is unfair to discredit operations which might have been successful at any earlier stage. Pauchet¹ discusses the whole subject with special reference to treatment. He gives no statistics, but his views embody the lessons of thirty years' experience of gastric surgery. He advocates operation as soon as the patient has recovered from the shock of the first haemorrhage if the diagnosis of bleeding ulcer is certain. Great stress is laid on the importance of this exact diagnosis before operation, since Pauchet ascribes the surprisingly high proportion of two-thirds of all cases of severe haemorrhage to diseases of the blood, liver, spleen, and other obscure "dyscrasias." He considers that it is not possible to secure haemostasis by operations such as gastro-enterostomy, jejunostomy, ligature of vessels at a distance, and cauterization: patients sometimes recover in spite of, and not because of, them. Pauchet recommends a limited partial gastrectomy and direct ligature of the vessels entering and leaving the ulcer, preceded by one or more blood transfusions and followed by a caecostomy and irrigation of the bowel—the latter on the grounds

¹ *Journ. Physiol.*, 1933, lxxx, 193

¹ *Bull. et Mem. Soc. Chir. de Paris*, 1933, xxv, 355.

that absorption of toxic albumin bodies from the decomposing blood is an important contributory cause of death. In an attempt to discover any factors affecting prognosis Allen and Benedict¹ have studied the records of cases treated in the Massachusetts General Hospital during the last twenty years. Out of a total number of 1,894 patients with duodenal ulcer, 628 had bleeding in amounts macroscopically recognizable, while 138 had severe haemorrhages producing collapse and acute anaemia. In this group there were twenty deaths; of these patients twelve bled to death without operation, and eight died following operations undertaken after all hope of spontaneous recovery had been abandoned. The average age of those who died was 56.3, and of those who recovered, 41.8. Below the age of 49 there were only two fatalities in the whole series. Contrary to general belief the number of previous attacks of haemorrhage had no prognostic value: 60 per cent. died during the first attack. The average time between the onset of haemorrhage and death was sixteen days. Allen and Benedict believe that some of these patients could have been saved by early operation. They suggest as a working rule that those who rapidly lose the benefits of transfusion after a second collapse should be given a large transfusion and immediately operated on, particularly if they are over middle age. They consider direct ligation of the bleeding vessels essential, and their operative technique in principle resembles that of Pauchet. The most notable facts that emerge from Allen and Benedict's analysis are the remarkably small mortality below the age of 50 and the hopelessness of operating on repeatedly bled patients. The subject is a debatable one, but in the absence of any really trustworthy guide to prognosis at an early stage (after which the information becomes less and less valuable) most surgeons are likely to maintain the attitude that it is not justifiable to endanger the safety of many in the hope of saving a few.

HISTORY OF DIETETICS

Recent discussions on dietetics add point to the saying—quite as true as the proverb it parodies—that what is sauce for the goose is not always sauce for the gander, and we are glad to be reminded by Dr. Robert Hutchison, in his stimulating article on the history of dietetics in this month's *Practitioner*, that "dietetics is really a very young branch of science." How young it is may be judged by the remark, quoted by Dr. Hutchison, of the Arabian Rhazes (850-932): "When you can heal by diet prescribe no other remedy." The wheel has come full circle, and modern dietists are now trying to work out the implications of the Arabian physician's saying. The nineteenth century, Dr. Hutchison writes, was the quantitative epoch of dietetics, but a quotation from Dr. James Hart of Northampton (1633), or the *Diet of the Diseases*, 1633) that the "outlandish root" potato was "Farre fetcht and deare bought and therefore good for Ladies" shows that even in the seventeenth century the cost of calories exercised the mind of the physician, though the word "calorie" was not coined until 200 years later. At the conclusion of his article Dr. Hutchison points out that, just as the importance of the calorie

was unduly stressed at the end of the nineteenth century, so is that of vitamins in danger of being overestimated to-day. This warning was also echoed in a letter to the *Times* of November 23rd, 1933, by Professor H. A. Harris, who said: "There is a danger lest we forget that all the substances so necessary to the animal economy, wonderful as is their separation in the laboratory, occur naturally in the fresh wholesome foods which constitute a balanced diet."

OBSTETRIC DIPLOMA FOR PRACTITIONERS

One of the main objects of the British College of Obstetricians and Gynaecologists has been, and is, to improve the standard of midwifery all over the country among general practitioners who wish to hold obstetric appointments in voluntary maternity hospitals and in those under public health authorities and to act as local obstetric consultants. After long consideration, and as the result of over three years' experience gained by its Examination Committee, the College, recognizing that the present training of students in obstetrics is insufficient to fit them for responsible work in maternity services, has decided to award a diploma (D.C.O.G.) to registered medical practitioners who have had special post-graduate training and experience in the subject and satisfy the examiners appointed by the College. The membership of the College, being intended for those aspiring to special practice in obstetrics and gynaecology, demands a larger and wider experience than is possible for those entering family practice. Many candidates for the membership have had to be rejected because they had insufficient training and experience, and for most of these candidates it is impossible, at the stage of their career which they have reached, to undergo further training and to hold further resident posts. Many of them will be suitable candidates for the diploma. A special regulation has been made for candidates whose names have been on the *Medical Register*, and who have been engaged in practice, for at least ten years. Copies of the prospectus and regulations may be obtained from the secretary of the College, 58, Queen Anne Street, W.1.

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* and *Epitome* have been printed; they will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or all of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

The report of the Departmental Committee on Sterilization is being issued on Thursday, January 18th, after we have gone to press with this number of the *Journal*. Reference to it must therefore be deferred until next week.

THE CHILDHOOD OF HELEN KELLER

BY

JAMES KERR LOVE, LL.D., M.D.

"A deeper import lurks in the legend told my infant years
Than lies upon that truth we live to learn."

(Quiller-Couch, in the *Oxford Book of English Verse*.)

"There was a time when meadow, grove and stream,
The earth and every common sight
To me did seem
Apparell'd in celestial light
The glory and the freshness of a dream."

(William Wordsworth, *Ode: Intimations of Immortality*,
from *Recollections of Early Childhood*.)

The above quotations speak to the existence, and in the first quotation the permanence, of early impressions gathered in childhood. They are from the experience of gifted but otherwise normal people, and may be taken as representing the experience of the average adult, who, however, would not express his recollections in such poetic fashion. I have quoted them to introduce an equally gifted woman who, as a child, suddenly lost the two great avenues by which impressions reach the mind. It may be that the study of such a case will give some light on the value of early impressions. I refer to Helen Keller, who was made completely blind and deaf at the early age of 19 months. Much has been written about the early years of Helen Keller, but I have her own assurance, and that of Anne Sullivan, her teacher, that no exhaustive examination has been made of Helen's first nineteen months, when she saw and heard.

Lately, when the guest of these ladies in the Scottish Highlands, I raised a question which has often interested me—namely, "The Story of the Frost King." This story, spelled into Helen's hand at the age of 8 years, when she could not possibly understand it, was unwittingly reproduced by her as her own at the age of 11 years. It was called a plagiarism, but this it was not, for Helen was unconscious of ever having heard it. But it was so well reproduced that its source could not be denied. Miss Canby, its author, thought it in some respects better than the original. What happened in Helen's mind during the interval of those three years "in the underground laboratory of her thought"? I do not know, but the problem suggested an inquiry into the question. What became of the impressions gathered into Helen's mind, and stored away somewhere, during the nineteen months of seeing and hearing? Were they lost or had they merely lost their labels (for the time at least)?

There are two or three physiological and clinical facts which must be stated before entering on the case of Helen Keller.

1. There is a hereditary tendency to use language, although it be only a sign language, in all the higher animals, including man.

2. There is in man a hereditary tendency to speak—although not to use any particular form of spoken language—and the centre for the acquisition of speech is Broca's convolution, near the juncture of the lateral aspect and the base of the brain.

3. It is probable that objects have little definite form in the eye, or sound definite meaning to the ear, during the first three months of life. The next eighteen months are, however, very fruitful in the acquisition of impressions, both of sound and of sight, and through repetition by parent and nurse most common objects are recognized by their names. After the first year many of these names are not only recognized but by successful imitation are repeated by the normal child.

4. Sudden deafness, when complete and when occurring during the first three years of life, is followed in a short time by the loss of speech. This occurs in two or three months, unless means are at once taken to perpetuate the speech. The names of objects get wiped out or the labels are lost.

5. Such lost speech may be resurrected by the teacher. It is easier to recover speech in such a child than to create speech in a deaf-born child. Every teacher of the deaf knows

this. The extent of the acquired vocabulary at 18 months or 2 years varies with the rate of development of the child, but is always less than that understood by the child.

(Note.—Preyer gives figures for the number of words used at 2 years as 100 to 1,000—probably about 400 or 500. These words are a much more recent acquisition than the knowledge or recognition of the things and actions they denote, and are therefore more easily lost should sudden deafness occur.)

Believing that some parallel might exist between the "Frost King experience," on the one hand, and the gap in Helen Keller's life from 19 months, when she lost her sight and hearing, and the coming of Anne Sullivan, when Helen was 7 years of age, on the other, I began a cross-examination of both teacher and pupil. Whether the parallel could be sustained or not was not of the first importance. If it suggested a useful line of inquiry good might come of the effort.

I have intentionally left Wordsworth's verse at the head of this paper incomplete, for he finishes thus:

"The things which I have seen I now can see no more."

But Wordsworth had an unbroken series of 'subsequent impressions' which obscured his earlier ones. Helen has none of this, except through the senses of touch and smell. Was this an advantage or not? It isolated or cut off her earlier experiences. It was a disaster to Helen. Had it any compensations for the student of child life? I hope to show that it had.

How far back does the adult memory go into the recollections of childhood? In my own case not earlier than the fifth year. In some of my friends it goes back to the fourth year; and in one or two to the third year.

In Helen Keller's case it certainly goes back to the second year. She is quite positive that she remembers a tremendous pain in her eyes and a fear of light. These, along with screaming and tossing about, were features of the illness which destroyed her sight and hearing. This evidence must be put in a class by itself. Helen remembers nothing more of this early seeing and hearing time. But the experience was a striking one, and may well stand out from all that went before or along with it. It needed no name or label. As we have seen, the names of things soon went—the writing was rubbed out—the label lost. But were the things the names stood for quite forgotten, quite lost? Because if not some light may be thrown on Helen's subsequent mental history. Even her present marvellous powers of description of nature may be in part accounted for. Given a skeleton of fact and a vivid imagination a blind-deaf person may become anything, even a poet, and Helen is essentially a poet. The best authority on this subject is, of course, Anne Sullivan, her teacher, who, along with Helen herself, brought out some interesting points, of which I quote the following.

Evidence of the Second Class

1. On Miss Sullivan's arrival, one of the first things Helen did was to take her teacher's hat, which lay on the bed of the room, and putting the hat on her own head went to the mirror and, preening herself, adjusted the hat to various positions. When Helen was a baby she was often put before a mirror to see herself and her blue eyes.

2. When Helen was given a pipe with which to produce soap bubbles, she, without any hint, put out her hand to feel for the bubbles—bubbles she could not see and had not been told about. It was known that during her seeing period she had, along with a little friend, produced such bubbles. Helen says that when she puts her hands into soap bubbles and the sun shines on them she feels them sparkle and quiver. Here is an association of touch with recollected sight.

3. Heat is always associated in Helen's mind with light. When she stands before a fire or radiator she always turns her face upwards as she did and does to the sun. This is an association in Helen's mind of heat with light or brightness.

4. When given a banjo, Helen at once began to twang the strings. Now in her father's house, which was a large one, an old nigger used a banjo much as a paper uses the bagpipes in Scotland. During her childhood this old nigger sat about the door and played the banjo and during her hearing period Helen heard the banjo and saw the playing of it.

5. Helen's father was a newspaper proprietor, but also a gentleman farmer who hunted and had dogs. Helen herself was attended by a black nurse. Helen's dreams, since she was able to express anything, have been visual. A common dream is of a person putting out her hand "to grasp me" showing evil intent, and this person is always black. As Anne Sullivan says, "Helen is not blind-minded."

In dreams, too, Helen is conscious of the eyes of other people and of animals. Fear, alarm, and astonishment are common in childhood. Here they are linked to a definite recollection. Helen Keller has discussed her dreams in *The World I Live In*. I quote the following apropos of what I have said above:

"In my dreams I have sensations, odours, tastes, and ideas which I do not remember to have had in reality. Perhaps they are the glimpses which my mind catches through the veil of sleep of my earliest childhood. I have heard 'the trampling of many waters.' Sometimes a wonderful light visits me in sleep. Such a flash and glory as it is! I gaze and gaze until it vanishes."

(Note.—It should be stated here that Helen Keller has no recollection of having used such childish words as mamma, daddy, tata, baba—the labial and dental words usually spoken by children in early childhood. Helen states that she thinks her dreams have perpetuated her memories of what she once saw and heard.)

With such a skeleton of nearly forgotten impressions, and with her remaining senses of touch, smell, and taste, Helen Keller, aged 7, met her teacher, Anne Sullivan, and then began the most remarkable educational triumph of which we have any record. Miss Sullivan had little to build on, for be it noted at once that Helen Keller's sense organs were not then, and are not now, more acute than the average. What takes place, then, in the blind or the blind-deaf is not a change in the terminal sense organs of the fingers or nose, but the better use of the impressions sent from the terminal organs to whatever exists inside the skull; call it mind, soul, or aggregation of grey matter with connecting fibres as you will. Dr. Tilney, in an exhaustive examination of Helen Keller's sense organs, has settled all doubt on that point as far as Helen is concerned.

The normal child goes on adding to his sense impressions after the age at which Helen had to stop. But he goes on with help other than his senses. His mother tells him fairy tales, he falls into the hands of a teacher who, in some sense, educates him: he reads books, and in a year or two his mind is so packed with information from various sources that it is not possible to say whether what he knows is from first-hand or second-hand, or from any further out source. Listen to Mark Twain on Helen Keller and the Frost King incident. "Substantially all ideas are second-hand, consciously and unconsciously drawn from a million outside sources and daily used by the garnerer with a pride and satisfaction born of the superstition that he originated them. Whereas there is not a rag of originality about them except the little discoloration they get from his mental and moral calibre and his temperament, which is revealed in characteristic phrasing." Even allowing that Mark Twain was in a temper and defending a heroine, what he says is substantially true. There is little originality in anything we either do or say.

Helen's perceptual world is very accurate for near objects. Take the case of a horse. She has passed her hand over its body, has fondled its nose and neck, and has had her affection returned. She knows the mould of its fetlock, the texture of its coat; in fact she knows all about it except its colour. She has ridden a horse, been thrown from it and got on its back again, and she is a poet; she might write a poem like Byron's *Mazeppa's Punishment* quite well. I do not think Byron tells us the colour of *Mazeppa's* horse. She has crawled into the newly excavated dwellings of the Picts in Orkney and Shetland, and come out with a better idea of bed and fireplace than those who saw the interiors. So much more accurate and memory-fixing is the sense of touch in the blind than that of sight, in most ordinary people.

For a general notion of the world beyond the reach of her fingers or her sense of smell, of course, Helen has to borrow, and she tells us how she gets the scaffolding of facts from her teacher and Miss Thomson. There is no hypocrisy about Helen Keller. It is here, however, that I believe Helen Keller resurrects the once vivid impressions of early childhood—those of colour and sound. Those impressions for a time have lost their names, but the percepts have not been lost. They have only faded and, with her imagination, she can paint a vivid picture. This world beyond the reach of her hand has been brought near her by Miss Sullivan. Her teacher has, on the banks of the Tennessee, made a toy world for Helen with sand mountains, and real water forming the associated rivers and lakes.

Helen is a good walker and climber, so she knows something about a mountain top, she is also a good swimmer and knows a great deal about the sea, and she has felt the rush of the air caused by the wings of a thousand birds at the Island of Nos in the Shetlands. Helen Keller therefore is not space-blind; she knew before her sight and hearing were lost all about a three-dimensional world, how things were either to one side or the other, above or below, and in front or behind one another. Guided by her sense of touch and that of smell her space-knowledge has been kept in operation. Then it must be granted that she had then, as she certainly has now, a wonderful memory—the Frost King incident proved that.

Lastly, she has had the whole attention, during nearly fifty years, of a fine teacher, who has devoted her life to a receptive pupil with this tenacious memory. Any teacher of the deaf or the blind will agree as to the advantage this confers. Indeed, every deaf child should have for some years a whole-time teacher. Unless Miss Sullivan had given her whole time to Helen we should never have had the educational result which continues to astonish the world.

Such are examples of the perceptual skeleton which Helen clothes with imagination and produces as a prose poem. One cannot live with her for an hour without the poet breaking out. Recently, on a motoring run in the Highlands, when the weather was changeable—the B.B.C. announcer would have called it "showers with bright intervals"—Helen said, "I feel the mist and the sunshine chasing each other on my face"; and again referring to the weather of the same day, "In Scotland one is always on the edge of the unexpected."

What I have written is not an attempt to explain the whole mind of Helen Keller; she has herself done this well in *The World I Live In*. I have tried to resurrect some impressions of her early childhood, which she could not recover alone because the names of such perceptions had been lost. But the impressions, the perceptions, were not lost, as she herself says:

"During the first nineteen months of my life I had caught glimpses of broad green fields, a luminous sky, trees and flowers which the darkness which followed could not wholly blot out. If we have once seen, the day is ours and what the day has shown."

The above quotation from Helen's book, *The Story of My Life*, is interesting. For two summers she lived in the brilliant sunshine of Alabama on her father's farm, where the main features of external nature were broad green fields, flowers, and a luminous sky, and where all the life of a farmyard completed her world. During those two summers she had her sight and hearing. There is no record that she was anything but a bright, ordinary child, and no first-hand reference can be got, for Helen's father died early, her mother has been dead some years, and Helen was the eldest child; but her subsequent development warrants the opinion that she was from the beginning an unusually bright child.

It is perhaps worth while emphasizing this point. In four months after Miss Sullivan's arrival Helen Keller writes letters which an ordinary seeing and hearing child cannot write after years of schooling. In seven months Mr. Anagnos of the Perkins Institution for the Blind wants a picture "of Helen and of her illustrious teacher

to grace the pages of the forthcoming annual report." In a paper like this I cannot quote those letters, but I pass on to one written to Oliver Wendell Holmes on March 1st, 1890, three years after Anne Sullivan's arrival, and beginning "Dear Kind Poet"; and this is Holmes's comment: "Anthropologist, metaphysician, and, most of all, theologian, here is a lesson which can teach you much that you will not find in your primers and catechisms. Why should I call her 'poor little Helen'? Where can you find a happier child?" Psychology was not so fashionable in Holmes's time as it is now, but I would add "psychologist" to his list. Clearly we are not dealing with an ordinary child in little Helen Keller.

SILICOSIS AND TUBERCULOSIS IN SOUTH AFRICA

REPORT OF THE MINERS' PHTHISIS BUREAU

A report on the work of the Miners' Phthisis Medical Bureau, covering three years, has been compiled by its chairman, Dr. L. G. Irvine, and is published by the Government of the Union of South Africa.¹ Since 1929 the number of routine examinations has grown rapidly. Assumption by the Bureau of direct responsibility for the periodical and initial examinations of non-European miners accounts for some of this increase, but the greater part is explained by the large number of examinations of European miners or of prospective recruits for mining. The Bureau is compelled to examine anyone who cares to apply for an initial examination before taking up mining work, and although the standard of health required is very strict the number of those approved is considerably above that which the industry can absorb at present; hence much of the work appears to be wasted. It is suggested that the present system will have to be modified if the industrial depression continues. At the request of the City Council of Johannesburg the Bureau undertook the routine examination of persons employed in rock drilling for sewer construction. Several well-marked cases of silicosis were discovered among these, and there were two deaths. Other municipalities have therefore been warned of the danger attaching to this kind of work, and of the need for rigorous control of such operations from the point of view of dust prevention.

INCIDENCE OF SILICOSIS

Whereas the average number of returns of compensation for this disease in the four years 1912 to 1916 was over 800, the combined number of all new cases of silicosis and tuberculosis with silicosis detected by the Medical Bureau during the three years 1929-32 among miners who had been at work since 1916 has averaged annually under 300. Since the number of miners employed underground was for both periods much the same—namely, about 11,000—these figures are fairly comparable, and indicate a decline in the incidence of about 60 per cent. It is pointed out, however, that the actual number of cases of silicosis in any year depends on factors which are variable. In the two three-year groups 1920-3 and 1928-31 the annual average was the same, namely about 251 cases, but between 1923 and 1927 there was a pronounced rise above this level. The most reliable measure of incidence is provided by the actual rates of liability to contract the disease shown by miners working in each successive year of underground service. These rates have undergone a marked, though not uninterrupted, decline during the past fourteen years. The general liability of the working

miner to contract silicosis was reduced between the triennium 1920-3 and 1931-2 by no less than 55 per cent. This Dr. Irvine regards as the true measure of the improvement. Yet the number of cases detected has shown no proportionate decrease, but rather an increase, which is attributed by him to two factors. A considerable proportion (but less than one-half) of the increase in cases in 1923-6 he attributes to changes in the standard of diagnosis and selection of early cases which were adopted by the Medical Bureau during that period as the outcome of improved radiological technique and accumulated experience. A still more important factor in this increase was the very marked rise since 1920-3 in the number of miners working in the later years of underground service, at which the incidence of silicosis is at a maximum. The actual figures are thus the net result of the operation of two conflicting influences: a decline in the liability to contract silicosis, and the progressive leaping up of miners in the later years of service. The first influence has now become dominant, and is of very encouraging import for the future. There has been much improvement in the environmental conditions and also a lessened liability of the individual to contract the disease.

PROGRESS OF THE SILICOTIC LESION

Returns are published in the report indicating the subsequent history of silicosis cases. The most serious feature of this condition is its progressive tendency. Three factors appear to be concerned in this. Even in the absence of infection or of further exposure to dust, a simple, uncomplicated silicosis often shows much advance, probably by reason of the amount of silica dust retained in the lungs. A final degree is reached, however, and the process is then arrested, unless an active tuberculous infection develops. Again, in the silicotic lung there exists a high potential predisposition to the ultimate development of active tuberculosis. This heightened susceptibility may be caused by reactivation of a pre-existing focus of tuberculous infection, or by a reinfection occurring simultaneously with, or subsequent to, the development of the silicotic lesions. Thirdly, in a lung significantly occupied by silica dust, a tuberculous infection commonly tends to develop atypically, with the production of chronic indurated lesions of mixed silicotic and infective origin. These are generally slowly progressive, and may become very extensive, but they also may, and often do, undergo long periods of virtual arrest. To these characteristic lesions the term "tuberculo-silicosis" has for many years been applied in South Africa. The excessive fibroid reaction which they present tends on the one hand to restrict and retard the spread of the tuberculous infection, both in the lung and to other organs, but, on the other hand, this reaction renders the infection less capable of an ultimate practical cure. Although, in consequence of this characteristic feature, the ultimate manifestation of active tuberculosis may be long delayed, the latter condition is by far the most common cause of death in cases of silicosis. The existence and the common concurrence of these factors explains the numerous variations in the development and character of individual cases. Those which are highly infective from the onset progress rapidly, some patients dying within a year. In others the disease may reach a condition of prolonged or virtually indefinite arrest. Nevertheless, the intrinsic tendency of silicosis to progress is on the average very pronounced and singularly uniform. It was hoped that with the introduction in 1919 of compensation for the ante-primary stage of silicosis, and with the removal from underground work of miners in the earliest detectable stage of the disease, the subsequent progression would be modified favourably and substantially. This expectation has not been realized. It would rather appear that the only definite advantage gained by the earlier diagnosis and removal of cases has been in the direction of slightly retarding, without in the long run substantially modifying, the intrinsic progressive tendency of the disease, at all events during the first five or six years of its course. The cases which progress to the secondary stage in the first few years after their detection are those in which an

¹ Government Printer, Pretoria. U.G. No. 22 1933 (35 61)

infective element is present and pronounced from the onset, and these years accordingly show the highest mortality. In short, while the medical and technical measures of prevention adopted have brought about a very substantial, though by no means complete, degree of control over the production of the disease, no corresponding measure of control has been gained over its progression. Hence, Dr. Irvine urges even more concentration of effort on prophylaxis, and for this there still appears to be much scope.

TUBERCULOSIS WITH SILICOSIS

Though there has been in the last seven years a decided fall in the number of detected cases of tuberculosis with silicosis, there has been a concurrent rise in the number of cases returned as simple tuberculosis, and of the open type. Figures are given which indicate that the liability to death is directly connected with the relative prominence of the tuberculous factor in the mixed as well as in the simple cases. An early conjunction of silicosis with tuberculosis is shown to be more rapidly fatal than a simple tuberculosis. In native workers the prevalence rates for tuberculosis, after reaching a maximum in 1926-8, have shown since then a definitely lower trend. The rates for tuberculosis with silicosis, after an initial rise, declined sharply, and the combined rate for both of these was in the past year the lowest on record. The prevalence rates for silicosis alone in natives have been since 1924-5 more or less maintained at a new and higher level than before, and in 1930-1 took a further upward turn. It happened, however, that during that year a special extensive radiographic investigation was made of all natives who had a cumulative underground service of over five years. This was thought to be the cause of the higher rate, and in fact there ensued a sharp decline in 1931-2. The earlier detection of cases of silicosis should reduce the prevalence of the more serious cases in which that condition is complicated by active tuberculosis, and the returns indicate that this is taking place. Nevertheless, Dr. Irvine concludes, the great preponderance among native miners of active tuberculosis, singly or associated with silicosis, emphasizes the cardinal importance of all efforts being devoted to the elimination of cases of communicable tuberculosis among the mine natives, and of bringing under control every occupational or other condition that can be shown to foster this infection among them.

Scotland

The James Mackenzie Institute

Investigations conducted at the James Mackenzie Institute for Clinical Research, St. Andrews, during the year ending July 31st, 1933, related to the alternating pulse, the state of the teeth in various age groups of children, and the condition of children entering school life at present in comparison with the condition found before the establishment of the child welfare scheme. It is mentioned in the annual report that an attempt by the Institute to trace in adults the definite initial symptoms of later disease has been disappointing. All the medical practitioners of St. Andrews are on the staff of the Institute, and it is now suggested that a combined effort on their part to follow up the large number of children whose early histories are accurately known might lead to valuable results. The public health work of the Institute is in the hands of general practitioners, who, it is remarked, are alone in a position to keep the populace under observation in health and disease. Since its foundation in 1919 the James Mackenzie Institute has set itself to conduct investigations with a view to speeding up the process of diagnosis, as the result of the collection of clinical information, and collating it with other lines of research. Although restricted latterly by financial diffi-

culties—expenditure during the year under review exceeded income by £188—the main lines of work have been pushed, and a considerable amount of valuable information has been collected, largely in the form of accurate histories of children from birth until school life begins. The population of St. Andrews is of a size permitting a knowledge of the circumstances of each patient. Since many of the inhabitants do not leave the city, persons can be observed for many years and records be kept of the early stages and later development of their maladies. It has been found that at present 60 per cent. of these records at the Institute are complete, notes having been added in steady sequence. Two papers by members of the staff were published in the *British Medical Journal* last year.

Stirling Mental Hospital

The sixty-first annual report of Stirling District Mental Hospital, dealing with the year ending May 15th, 1933, shows that at the beginning of the year there were 1,037 certified patients on the hospital register, including 583 men and 454 women. The number admitted was 238, which, with 159 discharges and eighty-four deaths, left 1,032 patients on the register at the end of the year. The number of certified patients under treatment during the year was 1,275, as compared with 1,274 in the previous year, and the average number resident was 1,045. With regard to admissions, the ages varied from 16 to 84 years, twenty patients being over 70 and the average age on admission being 42 for both sexes. Only thirty-nine of the patients admitted were described as being in average health; 161 were in indifferent health, and thirty-eight were in feeble health or were suffering from serious bodily ailments. There was acute mental illness with reasonable prospect of improvement in 101 patients, while 137 were suffering from confirmed mental ailments with little hope of ultimate recovery. There were twenty-seven cases of senile insanity, sixteen of general paralysis, eighteen of insanity with epilepsy, and four of mental enfeeblement following encephalitis lethargica. In seventeen cases the mental breakdown had followed serious bodily illness, and in eighteen there was a history of alcoholic excess, senility was present in twenty-seven cases, syphilis in sixteen, and epilepsy in eighteen. In twelve cases an inherited predisposition was elicited, and sixty-four patients had suffered from previous mental breakdown. In forty-six cases the mental breakdown had occurred at the critical periods of life, and seven cases were attributed to pregnancy and childbirth. In addition to the certified patients, there were twenty-three voluntary ones at the beginning of the year; seventeen voluntary patients were admitted and seventeen discharged as cured during the year. Of the latter, twelve returned home after a residence of three months. With regard to Service patients, there were forty-two certified and one voluntary, as at the beginning of the year. Of the 159 patients discharged, 110 recovered, giving the satisfactory recovery rate, calculated on the number of admissions, of 46.3 per cent. for both sexes. Of these, seventy were discharged within six months of admission, eighteen after twelve months, and twenty-two after more than a year's residence. The patients discharged unrecovered, chiefly by transfer to other institutions, numbered forty-nine. There were eighty-four deaths during the year, giving a death rate, calculated on the average number resident, of 8.4 per cent.; of these, seven were over 80 years of age and thirty-four over 65. The average age at death was 58 for both sexes. Disease of the heart was present in eighteen cases, diseases of the brain and nervous system in nine, acute diseases of the lungs in nine, and pulmonary tuberculosis in five. The report states that satisfactory results continued to be obtained in the treatment of general paralysis, and during the year nine patients

suffering from this condition were able to return home greatly improved. A tubercle-free herd of cows, supplying over 50,000 gallons of milk during the year, was maintained on the farm of the institution.

Glasgow Royal Infirmary

At the annual New-Year's Day meeting of the managers and nursing staff of the Glasgow Royal Infirmary, with Lord Provost Swan presiding, Sir James Macfarlane, chairman of the managers, said that in the past year trade depression had caused considerable anxiety to the management. During the year 16,564 patients had been treated in the wards, and 118,666 as out-patients with 389,207 attendances. The work had involved additional expenditure, with the result that the income for the year from all sources, including legacies, had fallen short of the expenditure by £6,000, and he therefore appealed for increased support. During the year sixty candidates had passed the preliminary State examinations in all subjects, and sixty-six had passed the final examination.

England and Wales

Bath Child Guidance Clinic

The second annual report on the Bath Child Guidance Clinic indicates the possibilities of prophylaxis and treatment of functional mental disorders in children, although there is a commendable absence of any tendency to draw unwarranted conclusions. In a prefatory note Dr. J. F. Blackett, medical officer of health and school medical officer, refers to the closeness of contact between this institution and the public health authorities. He invited Dr. R. G. Gordon, who is acting as psychiatrist and director, to incorporate in the report a study of the first hundred consecutive cases. Dr. Blackett points out that these abnormalities of conduct in children must have some effect on the education and school life of a child, and the education committee must therefore be an interested party. He adds that the ability to escape mental breakdown in later life depends often on these emotional stresses being dealt with at an early stage in life. The clinic uses the premises of the school medical department, and receives help from the department's paid staff. Dr. Gordon's study contains short clinical notes and some conclusions which seem to be emerging. He believes that there is no evidence of any sex factor in the aetiology. He defines four classes of cases: children who might have come into the hands of the police, those whose conduct interfered with the general harmony at home or at school, a scholastic defects group, and cases in which there was inadequacy or pathological symptoms in the children. The best results were obtained in the first and last of these groups, indicating that the clinic seemed to have done something to save certain of these children from mental and nervous breakdowns on the one hand and from criminal acts on the other. The group of scholastic defects, comprising cases of mental deficiency, epilepsy, and insanity, was the least promising. In half the cases there was loss of one or other of the parents or breaking up of the home. One of the difficulties in diagnosis, it is added, is a just appraisal of the respective influences of individual innate peculiarities and of environmental influences. In many cases the treatment mainly involved dealing with the parents or the school authorities. In no case was any elaborate analytical technique undertaken, owing chiefly to lack of time. Only exceptional cases are, however, considered to be in need of this line of therapy. There was a definite preponderance of children aged 10 to 11. It is pointed out that such defects of character as

truancy or stealing may be due to any of a large number of different causes, and that the delinquent has to be treated, not the delinquency. The conclusion reached after two years of work is that there are definite grounds for anticipating satisfactory results, and that such a clinic adds to the knowledge of mental abnormalities in adults as well as in children, but it is far too early yet to make any striking claims as to what child guidance activities of this kind can achieve, and how much illness or crime they can prevent.

Central Midwives Board

At the January meeting of the Central Midwives Board for England and Wales letters from the medical officer of health for Rotherham were read: (a) Enclosing his comments on the resolution of the Board in December last, with regard to the method of summoning medical aid in cases of subinvolution of the uterus, occurring after the midwife had left the case, and asking for the Board's observations thereon. (b) Enclosing a draft of a letter which he proposed to address to midwives in Rotherham in cases in which a health visitor discovered a suspected case of subinvolution. It was decided to reply that the Board could not make rules governing every set of circumstances which might arise in various parts of the country, and that it could not make rules governing the co-operation of midwives and health visitors, as clearly such co-operation would vary according to local conditions and needs. Further, that local difficulties could only be overcome by local measures, which were outside the scope of the Board's authority—for example, the solution suggested in the last paragraph of the letter. It was agreed to send the following replies to a series of questions contained in a letter from the county medical officer for Essex.

1. That if a midwife proposes to practise in the area of more than one authority, she must give notice of her intention to practise to each of the authorities concerned. (See Section 10 of the Midwives Act, 1902.)
2. That the midwife should notify all the local supervising authorities in whose areas she practises (in the event of having to notify under Rule E, 6) of her liability to be a source of infection.
3. That the routine inspection shall be made according to mutual arrangement.
4. That the authority which first hears of the liability to be a source of infection should suspend the midwife, and inform the other authorities, if known.
5. That there is no necessity for more than one authority to suspend a midwife, as, so long as a midwife is suspended, she cannot practise anywhere. The question of the payment of compensation is not a matter for the Board to decide.

With reference to an inquiry from the county medical officer of health for Worcestershire as to whether the Board approves the administration of chloroform capsules by midwives in the Lucy Baldwin Maternity Home, Stourport, there being no resident medical practitioners in the hospital, the Board agreed that the following reply be sent:

"That as the rules stand at present, the administration of chloroform in any form by midwives, otherwise than under the direction and personal supervision of a duly qualified medical practitioner, is regarded as treatment outside their province. A wide and extended trial of these capsules, under medical supervision, must be carried out before sufficient evidence can be accumulated to convince the Board that the use of chloroform capsules by midwives can with safety be sanctioned."

A letter had been received from the Minister of Health approving the existing rules of the Board for a period of six months from December 31st, 1933. Approval as lecturer was granted to Mr. Harold Carter, F.R.C.S., Mill Road Infirmary, Liverpool. The Board adopted the report on Part 2 of the Midwife Teachers' Examination, 1933, and the recommendations contained therein.

Mental Observation Wards

In the mental observation wards at the hospitals and institutions under the London County Council the total number of admissions in 1932 was 5,852 (2,690 males and 3,162 females). The distribution of these wards is being gradually reorganized. Patients in South London will shortly be concentrated in three large units, at St. John's Hospital, Battersea (62 beds), Constance Road Institution, Dulwich (70 beds), and St. Alfege's Hospital, Greenwich (number of beds not stated, but apparently about the same). The small mental wards at Lambeth Hospital and Newington Institution are to be closed as soon as certain enlargements at Dulwich take place. North of the Thames a mental observation unit for thirty male and thirty female patients has been established at the City of London Institution, Bow, and there are about eight other small units in association with hospitals and institutions. Some of these are being reconstructed and extended, while others have been, or will be, closed as the larger units become available.

India

A Maternal Mortality Investigation

The report has been recently received of a special investigation conducted by Dr. A. L. Mudaliar, second obstetric physician and gynaecologist to the Madras Government Hospital for Women and Children, into the causes of maternal mortality in that city. The inquiry, which lasted twelve months, continued from 1930 to 1932, but there was a break in the middle of about eight months. The form used closely resembled that recommended by the Departmental Committee on Maternal Mortality and Morbidity appointed by the Minister of Health. During the period of the investigation there were 26,207 births, and there were 436 maternal deaths, the maternal mortality rate being thus 16.6 per 1,000. If this high figure prevails in cities like Madras, where prophylactic facilities are not lacking, the condition in the more rural areas must be very much worse. The maternal morbidity and mortality problem is certainly worse in Madras and Southern India generally than in any of the Western countries, and it is suggested that in the city of Madras, with its already well planned schemes of maternity relief and numerous institutions and other amenities, the chief drawback is probably lack of concentration of effort. Certain causes of maternal death seemed to be on the increase—namely, abortion, eclampsia, and anaemia, particularly the form consequent on hookworm infection. It is urged that the need for an ankylostomiasis survey is pressing, and that dietary deficiencies probably play a considerable part in much maternal ill-health and death. The Departmental Committee's "primary avoidable factor" in connexion with maternal deaths was found to be concerned in 53.44 per cent. There was a relatively heavy death rate in primiparae and elderly multiparae; insufficient spacing of births is incriminated as a very definite factor also. In the large majority of fatal cases ante-natal care was either lacking or inadequate, and the connexion of this with the death rate was apparent. It is urged, therefore, that maternity institutions should make much more adequate provision for ante-natal supervision, and a committee has been set up by the Corporation of Madras to overhaul and improve the existing centres. It is hoped also that in the future there will be much more provision of ante-natal ward accommodation, since many cases examined were found to require institutional treatment. The heavy incidence of puerperal sepsis, often in cases where the

labour had been normal, indicates that more rigorous care must be exercised in supervising the outfits of midwives and warning them of the risks of infection. In institutions also there is evidence that insufficient care has been taken to discriminate between the suspect and the frankly septic cases, both of which, moreover, are not infrequently dealt with in wards accommodating uninfected cases. More active steps, it is added, should be taken to ensure treatment in hospital for cases of early toxæmia, the early signs of which should be more swiftly recognized than is at present usual. A well-thought-out scheme is needed for housing the less affluent middle classes and also the poor, for in the older parts of the city there is already serious building congestion, interference with the free passage of air through the narrow streets, overcrowding, and bad sanitation. Dr. Mudaliar sketches the lines on which an efficient maternity service should be planned, involving the co-ordination of the various existing services. He pleads for more research into the causes of maternal morbidity, pointing out that these problems are very different in Southern India from those in Western countries, and that in Madras there is available an immense amount of clinical material.

Leprosy in Ceylon

At the invitation of the Government of Ceylon Dr. Robert Cochrane, medical secretary of the British Empire Relief Association, devoted six weeks last spring to a careful investigation of the present position as regards leprosy in the island, and a report of his findings and recommendations has now been issued. It is pointed out that in Ceylon only the more advanced cases are discovered; the progress of those with early lesions is unknown, and their liability to infect others is under no sort of control. The disease does not, on the whole, appear to be a serious menace to the community, but unless changes are effected in the present control measures no improvement is likely. The restrictions with regard to segregation are thought to be too rigid, and the regulations concerning home isolation, observation, and the supervision of patients discharged from treatment centres to be too lax. In the Eastern Province leprosy does not seem to be spreading. The asylum at Mantivu, in Dr. Cochrane's opinion, was doing good work in an almost ideal situation, and with ample scope for expansion; it was handicapped, however, by too rigid regulations as regards leave permits, which militated against its popularity becoming widespread. In the Colombo municipality a number of leprosy children were seen, and this leads Dr. Cochrane to urge that the presence of lesions should not always be regarded as necessitating treatment. He believes that, unless there are signs of multiple infection, or of definite activity, no suspected case needs treatment. Apart from examining the contacts, no mention of the suspicion need be made to the parents, and, provided such a child is adequately watched, it has probably an 80 per cent. chance of developing no further lesion, while the suspected lesion will become normal in a few years. It is thought that the disease may be spreading in certain areas in Colombo, and a systematic examination of school children is advised in order that a due measure of supervision may be rendered possible. The Hundala Settlement did not appear to be suitable for the treatment of early cases, and here, as at Mantivu, Dr. Cochrane regrets that no attempt is made to separate the early neural cases from the cutaneous ones. He remarks that there is some evidence that an early neural case, especially in children, can become further infected by a cutaneous case, and pass from the non-infective to the infective type as the result of close contact. He criticizes the Leprosy Ordinance on the grounds that neural cases have been admitted, or re-admitted, to the asylum, which, according to present

knowledge, do not need segregation; that the criteria for the discharge of a patient have generally not been strict enough, and that the granting of home isolation—a provision made to obviate segregation—has resulted in an unsatisfactory state of affairs. The setting up of a Leprosy Board is advised, with a view to its undertaking, among other responsibilities, to decide whether any given patient needed isolation or treatment, or both. Dr. Cochrane considers that more attention should be paid to the examination of contacts, that the specific treatment for leprosy should be made available at all hospitals in rural areas where the disease is prevalent, and that a special prevention centre should be organized for the Colombo municipality. Among other suggestions put forward is one proposing a voluntary institutional system along lines similar to those on which voluntary mental hospitals are conducted in Great Britain. Attention should also be paid to the instructing of medical students and graduates to view leprosy in the right perspective. Educational propaganda should be conducted, and the public should be led to view leprosy as a curable condition if early treatment is given, as not always infective, and in no way more unpleasant or disgraceful than other diseases. Survey officers should be charged to ascertain as accurately as possible the incidence of leprosy in Ceylon, and to organize protective measures in areas where there is evidence of the spread of the disease.

CORRESPONDENCE

Blindness due to Myopia

SIR,—The article on the control of school myopia, by Mr. Arnold Sorsby (*Journal*, October 21st, 1933, p. 730), indicates the varying points of view from which myopia can be surveyed. I venture to submit some facts which have come under my notice, and which are, indeed, difficult to explain by the conventional theories.

I have prepared an analysis of the causes of blindness, based on an examination of 192 persons admitted to the Royal Victorian Institute for the Blind from 1901 to 1923, and 226 persons admitted from 1923 to 1933. In the first series myopia accounted for one case of blindness. In the second series myopia headed the list with a total of thirty-one cases—that is, 13.5 per cent. But I am tempted to draw attention to some of the peculiar features of the second series. Children, whose ages are given, possessed myopia of high grade. For example:

Age	Degree of Myopia			
3	3 D - 1 D
3½	15 D - 15 D
6	10 D - 9 D
7	13 D - 15 D
10	15 D - 14 D

It is obvious that the use of the eyes for near vision cannot be a factor in producing or increasing myopia in children of the lower ages. Why should a child 3½ years of age suffer from myopia of 15 D in both eyes? The prevention of myopia really involves the difficult question of eugenics. Mr. Lang and I, many years ago, found myopia in domesticated animals, but only twice in wild animals. Two monkeys were so affected, but we could not ascertain how long they had been in captivity. It is, of course, obvious that the use of the eyes for near vision cannot have produced myopia in domesticated animals. It is difficult to understand the theory of departure from the mean as an explanation of these conditions in very young children. In the older cases the maximum recorded was 31 D. In some cases there was evidence of the stigmata of degeneration of various kinds,

but sometimes without any evidence of malnutrition. Such cases of myopia really represent a malignant uncontrollable disease.—I am, etc.,

Melbourne, Australia, Dec. 1st, 1933. JAMES W. BARRETT.

Inheritance of Mental Deficiency

SIR,—In his interesting account of an incestuous family in which the parents were brother and sister, the father suffering from general paralysis and dementia, the mother from feeble-mindedness; Dr. L. S. Penrose (*Journal*, January 6th, p. 10) finds difficulty in explaining why two of the three children are apparently of normal mentality up to their present ages of 17 and 7 respectively.

If the father was able to drive a cab, join the Army, proceed to South Africa, and afterwards work his passage home, he can hardly be supposed to have been feeble-minded. As insanity appears to be inherited independently of feeble-mindedness, a mating between this brother and sister might be expected to produce some children of normal mentality, even although, as appears very probable, the brother was carrying a recessive gene for feeble-mindedness. On the simplest assumption one might expect half the children to be normal and half mentally defective (apart from the dementia, whose inheritance is unknown). Now two of the children appear to be mentally normal, but it is quite possible that the eldest, who died at the age of 2½ years, was a mental defective.

Dr. Penrose's final suggestion, that possibly the environment of these children was so much better than that of their parents as to account for the normal mentality of two of them, seems hardly worthy of serious consideration. At the same time, our debt to him is great for the careful way in which the facts have been investigated.—I am, etc.,

R. RUGGLES GATES, F.R.S.

King's College, Strand, W.C.2,

"Bornholm": An Alternative

SIR,—Undeserved harm, in the judgement of the population and Government of the island, was formerly done to Malta by the indiscriminate use of the term "Malta fever," and Mr. E. A. H. Jay should be supported in his plea (January 13th, p. 79) to spare the island of Bornholm, while there is yet time, from a similar fate. At the International Office of Public Health in Paris we learnt from Dr. Madsen in 1932 of the outbreak which had occurred in Bornholm in the summer of 1930, and had been carefully described by Dr. E. Sylvest, as well as of the parallel occurrence of the same disease in other parts of Denmark. Since that date we have had from the same authority regular information regarding its continuance and its characteristic seasonal prevalence (with maxima in the autumn) in the same country, and accounts also of its prevalence in Sweden. The identity of the Danish epidemics with earlier outbreaks, such as those noted in the references attached to Dr. Pickles's paper (*British Medical Journal*, November 4th, 1933, p. 818), has always seemed clear, while recent individual cases or small outbreaks elsewhere than in Denmark and Sweden have since been reported.

In dealing with the subject the Committee of the International Office of Public Health has frequently experienced the difficulty of name, but by general consent the disease now appears in its agenda as "epidemic myalgia." This has proved sufficiently convenient and distinctive—I am, etc.,

The Nutrition Report

SIR,—I thank you for the publication of my letter about the price of food and your comment thereon. So long as it is understood that the correction of the price of only one item—milk—to current prices would raise the cost of the diet for a man, wife, and three children (No. 14) by 1s. 6d., nothing remains to be said on this point.

The discussion has entered a new phase with the appearance of the Ministry of Health Circular 1370, which criticizes the allowance of 3,400 calories and 50 grams of first-class protein. The question immediately arises whether there is evidence that health can be maintained, under ordinary working conditions, on lower scales. It is true that the average intake of the working-class is about 3,000 calories per adult man. But it is also true that those who can afford it take more; also that the National Service Medical Boards found only one man in three perfectly fit and healthy, and that the tuberculosis death rate in working-class districts may be five or ten times as high as in well-to-do neighbourhoods. The committee appointed by the British Medical Association appears justified in regarding standards under which such results are possible as inadequate for maintaining health.

There is another point. The diets of which the estimated costs were published in the *Week-End Review* of April 1st, 1933, conformed to the standards laid down in Circular 1370. The results show that full unemployment benefit is insufficient to pay for adequate food for a family, together with the other necessities of life, even if the diet is calculated on this lower scale.—I am, etc.,

Sawbridgeworth, Herts, Jan. 14th.

JOHN MARRACK.

* We omitted to mention in our comment on Dr. Marrack's letter of January 6th (p. 36) that the price of milk given in the report of the Nutrition Committee was the price current at the time the investigation was carried out. The regulations laid down by the Milk Marketing Board have come into force (October 6th, 1933) since then.

The New Cancer Problem

SIR,—No one who has followed the history of cancer research with any attention but must have been struck with the contrast between the confidence which animated it at the beginning of this century and the state of depression into which it has now fallen. This depression was noticeable at the meetings of the International Cancer Congress in 1928, and was given expression to by Professor Ewing when he stated that "the history of this research might well suggest that the problem of the nature of the tumour process is at present unsolvable."¹ As a fact, words to this effect had already been used by Sir Lenthal Cheate,² and were afterwards repeated by Professor Nicholson,³ both of whom look upon the problem of the deeper causes and nature of cancer as comparable with that of the nature of life itself, or, in a word, as insoluble.

And so, after centuries of experience and of the recording of facts; after a century of close observation and investigation, culminating in a third of a century of intensive experimental research by all the great civilized nations, we are told by those best qualified to judge that there is no more prospect of clearing away the mystery of the origin of cancer than there is of answering the riddle of the origin of life, or indeed of perpetual motion, or of squaring the circle. So far from having solved the problem we are now suffering from the demoralizing effects of repeated defeats, and in addition are faced with

a new problem, the new problem being to find the reasons for these devastating failures. And here, Sir, I come to the object of this letter, which is to call attention to this new problem and to the necessity for dealing with it before we can regain our morale and continue our attacks on the main problem with reasonable prospects of success.

There is much to be said for the belief now held by many oncologists that the chief cause of this new obstacle to progress is the present dominance of experimental research over clinical and pathological investigation of cancers in man. Instead of being the servant research has become the master. The tail now wags the dog. The cart has been put before the horse. How obstructive this is to all progress may be gathered by noticing what happens when there is a conflict between evidence from clinical sources on the one hand and that of experiment on the other. Invariably the evidence from the mouse claims precedence over that from the man. And this dominance of research may be noticed even when the point at issue is of considerable importance and has passed the tests of many years of practical human experience. Thus the doctrines implied in Cohnheim's embryonic tests, the facilitating effects of age and degeneration, the increase of cancer with increasing civilization, are all now rejected by laboratory oncologists for no other reason than that they cannot be made to fit in with the "findings" picked up in the course of experiments with fowls and mice.

Such a smashing of cherished beliefs would not so much matter were they mere idols, serving no useful purpose, and were it not for the enormous prestige of research, now widely regarded as authoritative in all that concerns cancer in both mice and men. As a fact, the examples just mentioned are conspicuous, well-grounded landmarks, from which bearings can be taken for advancement into new territory in the science of human oncology. Without them the explorer is lost, and can only wander round in circles in a way often to be noticed in the records of laboratory research.

In these circumstances of defeatism and confusion surely the time has come when those interested in this terrible visitation of cancer should no longer be deterred by any consideration but that of humanity and public interests from asking for the credentials of those who are responsible for these autocratic decisions. On what ground is this authority based? Is it upon the reliability and success of experimental compared with clinical methods? Certainly not; for we all know that so far as human oncology—the only thing that counts—is concerned, the student of human cancer can point to great and solid achievements in matters of structure, of diagnosis, and of treatment; whereas oncologists of the fowl or mouse can claim nothing but a record of hard work, great ingenuity, and unbroken failure. In the words of Dr. Woglom,⁴ himself one of the greatest and most respected of researchers, "the study of cancer, instead of affording an understanding of the nature of the disease, has opened up new problems which before were not even conceived." When, therefore, the experimentalist comes forward as the supreme arbiter and authority on all that concerns the study of human cancer, he lays himself open to the retort that his claim is no better founded than is that of the washerwoman who claimed to be an authority on the upbringing of children on the ground that she had buried nine. We are left to presume that the immense influence of the research worker is based on his official position, his generous support by the public, the prestige conferred upon him by the previous successes of bacteriologists, and, above all, by the ability, high character, and devotion of those who tread the unprofitable mills of cancer research. The colossal amount of literary material thrown up by the laboratories is also very impressive.

¹ *Third Internat. Cancer Congress*, 1928.

² *Lancet*, 1924, i, 1152.

³ *Ibid.*, 1932, i, 385.

⁴ *A Study of Experimental Cancer*, 1933, p. 273.

There seems to be a general impression that the special qualities which make a successful worker in mouse cancers—as this success is now estimated—are also those suitable for the adoption of large comprehensive views of cancer in man. Yet, so far from this being the case, both reason and experience suggest that the reverse is the truth: that close, painstaking, minute research in a laboratory is not conducive to the right understanding of large sociological problems involving questions of food or of civilization or race. Indeed, it would even appear that the more eminent a man in the little world of research the less is he fitted to give an unbiased or reliable opinion in matters concerning cancer of human beings. And there would be no difficulty in finding instances pointing to the truth of this statement.

The conclusion to which we appear to be driven is that, in order that this new problem of cancer should be solved, no more need be done than that the experimental oncologist should be asked to confine his attention to the work which he is now carrying out so brilliantly and so successfully among tumours of the lower animals, and should no longer concern himself with the tumours of man, a branch of oncology in which he has met with no success. And when the evidence from these two sources clashes, as it so often does, it seems nothing but just that the man should rank higher than and take precedence over the mouse, instead of the reverse, as is now the case. If this is done, may I venture to prophesy that the great central problem of cancer, no longer obscured or made difficult by the clouds and winds of useless controversy, will then not only be clearly seen, but will be attacked with far better prospects of success than has hitherto been the case.—I am, etc.,

Reading, Jan. 14th.

HASTINGS GILFORD.

Some Factors which Regulate the Uterus

SIR,—In an annotation on "Some Factors which Regulate the Uterus," in the *Journal* of January 6th (p. 38), mention is made of an article¹ of which I was a joint author. I would suggest that, on reading this commentary, it is difficult for anyone, other than those conversant with the original work, to separate the views there expressed from those put forward in the paper read at the ninth British Congress of Obstetrics and Gynaecology. It seems beyond question, however, that criticism of our work is implied, and I therefore feel impelled to correct any misunderstanding which may have arisen.

In spite of the statement to the contrary, it must be pointed out that, in the work in question, no assumptions were made on results obtained by *in vitro* experiments. Moreover, throughout the paper great emphasis was laid on responses which varied according to the different (that is, *in vitro* or *in vivo*) experimental methods employed. With regard to oestrin,² I was among the first to point out that this principle has no oxytocic action when tested on the isolated uterus, yet in the living animal it invariably produces, after a latent period, strong uterine contractions. This fact is now common knowledge, and is, moreover, emphasized in our latest work, so it is difficult to understand how anyone reading the article could accuse us of making assumptions on the results of *in vitro* experiments. This does not mean that such methods of investigation are valueless, but, rather, that such procedures must be carried out by those who have sufficient experience and knowledge of possible discrepancies to make them cautious as to the manner in which they interpret such experiments in terms of human physiology and pathology. It seems almost unnecessary to add that, although *in vitro* tests were made on many occasions, our work, for the most part, was carried out on living animals. Here again the same caution in interpreting results was exercised.

The annotation also infers that we are unfamiliar with the fact that impurities present in hormone preparations are a likely source of error. In reply to that may I refer to a paper read in 1931,³ in which it was shown that use of an impure oestrin preparation had led to erroneous results obtained by other workers? It is, of course, a well-established fact that, if both ovaries are removed from a pregnant woman, gestation continues without interruption, and is terminated by normal parturition. The annotation in the *Journal* quotes only one instance of this, and yet it is no exaggeration to say that most gynaecologists have encountered cases illustrating this phenomenon. The annotation appears to suggest that this undeniable fact makes it unlikely that oestrin, which is generally regarded as being a secretion of the ovary, can affect the course of pregnancy. It must be remembered, however, that it has not yet been proved that the large amount of this hormone found in the circulation during pregnancy has its origin in the ovary. On the other hand, it has been shown by several observers (Allan and Dodds,⁴ Szarka,⁴ Amati,⁵ Jeffcoate,² and others) that removal of the ovaries from a woman during pregnancy has no effect on the amount of oestrin found subsequently in the blood or urine of the patient. The explanation of this occurrence is a matter of dispute, but my personal view (this is not shared by my fellow authors of the paper under discussion) is that the oestrin is secreted by the placenta and not by the ovary during pregnancy. Nevertheless, evidence is accumulating to show that there may be more than one substance capable of producing oestrin in ovariectomized animals, so in the present state of our knowledge it is unwise to be too dogmatic on this point. Whatever may be the explanation, it is certain that an "oestrin-like substance" continues to be formed in, and excreted from, the body after both ovaries are removed from a pregnant patient, and that the occurrence of normal labour after bilateral oophorectomy in Man is no evidence that oestrin is not an important factor in determining the onset of labour and the nature of the ensuing uterine contractions of parturition. At this juncture a very interesting phenomenon may be mentioned. In animals such as the rabbit bilateral oophorectomy at any time during pregnancy is followed by abortion or premature labour. It is noticeable that such animals have no demonstrable amounts of anterior pituitary hormone(s) in the body fluids or placentas during pregnancy. This is in sharp contrast to the state of affairs found in the human being, and is additional evidence to suggest that, in Man, the anterior pituitary hormone(s) probably assist(s), or replace(s) the corpus luteum in inhibiting uterine contractions during gestation. The final criticism put forward in the annotation is that, if the oxytocic principle of the posterior lobe of the pituitary is a factor in causing the onset of labour, why should the pituitary gland of the male contain as much of this hormone as does that of the female? This argument appears to be singularly illogical, and it is absurdly easy to ask any number of such questions. For instance, why does the anterior lobe of the pituitary of the male contain an active principle capable of producing lutein tissue? or, why is it possible to obtain substances indistinguishable in their action from oestrin, from the testis of the male or even from plants? Surely the fact that one can obtain an oestrogenic principle from certain flowers or trees does not prove that oestrin is not responsible for changing the human endometrium from the post-menstrual to the interval phase. Nor does the isolation of an oestrus-producing hormone from the testis exclude the possibility, or rather probability, that oestrin affects uterine contractions in the female. May I add that your annotation would have provided a question more difficult to answer if it had asked why pregnant

animals in whom the pituitary body has been removed experimentally have been shown to have normal confinements at term? In conclusion, I should like to point out that most of the arguments put forward here are clearly expressed in the original paper by Professor Blair-Bell, Dr. Datnow, and myself.—I am, etc.,

Liverpool, Jan. 8th.

Control of Metastases in Breast Cancer

SIR.—I am sure all those of your readers who have studied the reports available of the recent congress of the British Institute of Radiology will have noted the scanty reference made to the question of "metastases," and thanks are due to Dr. S. Gilbert Scott for drawing particular attention thereto by his letter published in your issue of January 6th. All experienced observers of cases of malignant disease, and not merely of cases of such disease of the breast only, will agree with him that "it is the want of control of metastases which is the cause of failure to cure cancer." Meyer, in his work on cancer, graphically describes the "far-distance effects," as he terms them, and indicates how great an effect these new foci have upon the prognosis of the particular case.

I think all will agree also with Dr. Scott in regard to the ideal to be arrived at, which ideal is also well described by Meyer as "a therapeutic plan worked out to destroy in the system of the patient in one procedure everything present therein that pertains to cancer—that is, predisposition, precancerous phenomena, tumour, disseminated cancer cells, and metastases." Up to this stage I think there will be universal agreement with Dr. Scott, but when he states that this cannot be accomplished, I think he is too readily belittling the value of the time, labour, and, especially, money which has been spent upon cancer research work under very distinguished auspices in this and other countries—with far too little result, I admit, for the expenditure incurred, but still surely with some.—I am, etc.,

London, W.I, Jan. 6th.

The "Acute Ear" in General Practice

SIR.—It is only because the acute or subacute ear is primarily the concern of the general practitioner that I, as a G.P., venture to point out what I consider to be an important omission in my friend Mr. Guthrie's instructive paper on the acute ear in your issue of January 6th (p. 4).

A certain number of cases of "latent" otitis media present a varying degree of enlargement of the tonsillar group of lymphatic glands. This enlargement may be very marked indeed, and may or may not be associated with pyrexia or pronounced disturbance of the general health. Earache is often entirely absent. In the absence of tonsillitis, enlargement of the tonsillar glands should always lead one to examine the ear. As a rule there will be absence of the light reflex, mentioned by Mr. Guthrie, and alteration in the colour and appearance of the membrane, usually without actual bulging. Incision of such a drum will invariably result in a free discharge within twenty-four hours, the rapid subsidence of the lymphadenitis, and a return to normal health.

I do not doubt that this is a matter of common knowledge to ear specialists, but I have not seen it mentioned in textbooks or in the frequent papers on otitis media.

I have had to find it out for myself, and think that it is a point that should be placed prominently before students and practitioners.—I am, etc.,

Cheadle, Staffordshire, Jan. 8th.

Pruritus Ani

SIR.—In your issue of December 30th, 1933 (*Epitome*, para. 478), there is an abstract of an article advocating and describing elaborate surgical treatment for pruritus ani. The reference to extensive hypertrophy and oedema of the skin can surely be appropriate only to a very late stage of the malady—one which should never be reached unless through some extraordinary failure on the part of the patient to seek appropriate advice.

It is now generally accepted that the great majority of cases of pruritus ani are readily curable by a few mild applications of x rays, combined with special attention to the cleanliness of the parts. The total dosage, applied over two or three weeks, need not as a rule be equal to that given in a single sitting in a case of ringworm. Consequently there is not the smallest risk of skin irritation. Cases associated with severe piles will, of course, require operation, and in some instances the condition is a manifestation of neurosis.

In the female, where the vulva may be involved, even to the point of a leucoplakia, more vigorous treatment may be necessary—that is, a hard, filtered radiation, both on the diseased parts and on the lumbar spine. Many such patients, though they are often elderly and depressed to the verge of suicide, nevertheless do very well under suitable x-ray treatment.—I am, etc.,

London, W.I, Jan. 11th.

F. HERNAMAN-JOHNSON.

Continuous Intravenous Saline

SIR.—I was glad to see the article by Mr. Hamilton Bailey and Dr. Carnow on continuous intravenous saline in the *Journal* of January 6th (p. 11). This method, which has been in almost constant use at the Northampton General Hospital since June, 1931, of giving saline to shocked patients deserves the widest publicity, as it constitutes an addition to our armamentarium of the very greatest value. Of course ordinary intravenous saline has been given to such patients for a great number of years, but the usual practice was to give one or two pints of saline by means of a needle, tube, and funnel, and when this had been run in, and the patient's pulse thereby greatly improved, the needle was withdrawn and the patient left in the hope that this illusive recovery would be maintained. Or, more often, reliance was then placed on some form of rectal saline. In too many cases the improvement was found to be only transient, and in about two hours the collapse had recurred, sometimes with a fatal result.

The results from continuous intravenous saline are entirely different: there is no secondary collapse and no risk of overloading the right side of the heart. It is the introduction of a Ryall's drop indicator that makes all the difference. The fluid is introduced so slowly that excretion can keep pace with the inflow once the circulation has recovered, and ten pints in twenty-four hours is a fair average of the amount of fluid that can be introduced. We have found that warm saline flows better than cold, and for this purpose an electrically heated irrigator, such as Paterson's, is invaluable. The effect on the body temperature of warm saline is, I agree, quite negligible, as the fluid goes in so slowly, but cold saline causes contraction of the vein and sometimes stops the flow.

In conclusion, may I refer to another invaluable weapon which can be used in cases of obstruction and peritonitis? I believe that it entirely obviates the necessity for a high jejunostomy for these cases. I refer to the continuous drainage of the stomach by means of a Ryle's tube, a Woulfe's bottle, and a suction apparatus, such as a Sprengel's pump. Post-mortem examination of patients who have died from obstruction or peritonitis often show a hugely dilated stomach, and it was this striking fact which induced me to use this method originally. I believe that by keeping the stomach constantly empty the upper part of the small intestine, if not the greater part, can be freed of stagnating contents, and the prospect of re-establishing normal peristalsis thereby greatly improved. Intelligent patients have told me that the relief is indescribable, and some of them have taken complete charge of the tube themselves, taking it out and replacing it according to their sensations of epigastric fullness or otherwise. Another advantage is that, once the stomach is empty, the patient can drink without danger, as any water that cannot be absorbed is removed by the Ryle's tube, and, in fact, helps to wash out any small intestine contents that may have regurgitated into the stomach.

By these two simple methods of treatment—the continuous saline infusion which prevents dehydration, and the continuous emptying of the stomach which prevents acute dilatation of the stomach and drains a considerable portion of the small intestine—we can, I believe, do something to lower the mortality, which has remained stationary since 1924, from obstruction and peritonitis.—I am, etc.,

London, W.1, Jan. 8th.

B. L. LAVER.

Painful Injections: An Avoidable Cause

SIR,—It is certainly valuable to be reminded by Dr. Bousfield (*Journal*, January 13th, p. 76) that spirit may cause pain, but sterilization by boiling leaves the syringe wet, and therefore unsuitable for the accurate measurement of insulin, etc. Sterile and completely dry instruments can easily be obtained if syringe and needle, which have been kept in spirit (industrial spirit with 1/4 volume distilled water), are rinsed with ether immediately before use. The ether is aspirated through the needle from a small bottle, and may be used repeatedly. The last traces of ether are quickly expelled by aspirating air. Immediately after use syringe and needle are rinsed with water, if possible directly from a hot-water tap.—I am, etc.,

London, W.1, Jan. 13th.

F. E. LOEWY.

Rest in the Treatment of Neuroses

SIR,—In reply to Dr. Kemp's kindly criticism (*Journal*, January 13th, p. 79) of my letter of December 30th, 1933, and his specific query: As regards the first I had in mind, at the time of writing, only that class of sufferer from mental illness who was able to afford or was given the time for treatment and, even though at times with difficulty, had the wherewithal to pay for it. To go fully into the question of the crying need for the provision of adequate treatment for the large number of sufferers from mental illness who are in the position of Dr. Kemp's patient—"a case of dyspepsia of emotional origin"—I would, I fear, occupy more space than perhaps you, Sir, feel able to allow me. With regard to Dr. Kemp's query as to how I should treat this patient with "dyspepsia of emotional origin," who would certainly lose his job if he had "to go sick for a month," I am afraid I must confess that I should not be able to treat him at all. I am frequently asked by neighbouring practitioners to see "neurotic" panel patients or others in similar circumstances to Dr. Kemp's patient, and in far too many instances I have regretfully to report that, while much

might be done in more favourable economic conditions or where adequate treatment of this social class of patient was available—as it now is for similarly placed patients suffering from almost every other illness under the sun—in existing circumstances I can suggest nothing helpful.

The Mental Treatment Act, 1930, confers on local authorities the power to establish clinics for the treatment of mental illness. Over three years have now elapsed since the Act came into operation, but only one local authority here and there has made any attempt to make use of the powers conferred on them all. Cannot the general practitioner in his own interest, as well as that of his "neurotic" patients, either through the local Branches of the B.M.A. or by means of personal influence with individual members of his local authority, induce the latter "to get a move on"? So long as local authorities do not have the crying need for such clinics pointed out to them, and unless the medical profession makes the need known to them, there seems likely to be many more years of unnecessary suffering in store for patients with mental illnesses, while those suffering, in many cases, incomparably less pain and distress from almost every form of physical illness are provided with every known means of diagnosis and treatment free of cost. The best place for these clinics would seem to be in connexion with local hospitals or in separate buildings. I believe in a few cases they have been opened in connexion with mental hospitals. Till the public are sufficiently educated to realize that there is no disgrace in acknowledging a mental illness, this latter situation for a clinic seems apt to defeat its own object. The clinics should be provided with a few beds for such patients as in the first instance are not in a fit state of health to attend the clinic as out-patients. The great majority would be able so to attend, but without in-patient beds the clinic would lose a good deal of its usefulness.—I am, etc.,

J. W. ASTLEY COOPER.

Middleton St. George, Co. Durham, Jan. 15th.

Left-sided Stance for Urethral Instrumentation

SIR,—Your correspondent Mr. Alex. E. Roche says that he cannot understand what advantage is gained by a right-handed operator standing on the left of the patient. If a curved instrument is to be passed and the proper technique employed, a right-handed person, holding the instrument in his right hand, but standing on the right side of the patient, would of necessity cross his hands, and so assume an unnatural, therefore awkward, and uncomfortable position.—I am, etc.,

London, W.1, Jan. 13th.

M. W. BROWDY.

"Road Dangers"

SIR,—I have no wish to see this discussion, which was begun by Dr. G. Jones and not by myself, degenerating into the usual "pedestrian v. motorist" controversy, which would be out of place in your columns. May I, however, restate my opinion, which I hope I am not alone in holding, as follows:

If it is a fact that the work of many hospitals and of many medical men is being seriously hampered by their attention to the victims of road accidents, for which they receive an inadequate financial reward, then I consider it would be more in keeping with the functions and traditions of the medical profession for its members to try to obtain a diminution in the number of accidents rather than to agitate for more hospital accommodation, an enlarged ambulance service, and some financial machinery for payment.—I am, etc.,

London, N.W.8, Jan. 15th.

R. J. CLAUSEN.

Obituary

SIR DONALD MACALISTER, Bt., K.C.B., M.D.,

D.C.L., LL.D., D.Sc., F.R.C.P.

Chancellor of the University of Glasgow; late President of the General Medical Council

With the death of Sir Donald MacAlister, on January 15th at Cambridge, in his eightieth year, there passes an outstanding figure from the world of medicine—a man who held many high offices and impressed his personality upon the public life of his time. In 1929 he retired from the Principalship and Vice-Chancellorship of Glasgow University, and in 1931 he resigned the Presidency of the General Medical Council after occupying that position for over twenty-seven years.

Donald MacAlister was born at Perth on May 17th, 1854, the eldest son of Donald MacAlister, of the ancient family who were keepers of Tarbert Castle, Argyllshire. His brother, J. Y. W. (afterwards Sir John) MacAlister, was secretary of the Royal Society of Medicine from the time of its formation, in which he played so large a part, until 1925. Donald's early education was at Aberdeen and at the Liverpool Institute, whence he passed to St. John's College, Cambridge, with a mathematical scholarship, having qualified also for scholarships at Balliol and Worcester, Oxford. At Cambridge he won the Herschel prize in 1876, and in the following year was Senior Wrangler and First Smith's Prizeman. Taking the B.Sc. (London), in his stride, he became mathematical master at Harrow, but not long afterwards entered as a medical student at St. Bartholomew's Hospital, where he was appointed lecturer in natural philosophy in 1879; two years later he graduated M.B. (Camb.), and obtained the M.R.C.P., proceeding M.D. in 1884. He was elected a Fellow of the Royal College of Physicians of London in 1886, and gave the Goulstonian and the Croonian lectures in the two following years. He returned to Cambridge as Fellow and lecturer of St. John's, and from 1889 to 1908 represented that university upon the General Medical Council, during which period he was senior tutor of his college and physician to Addenbrooke's Hospital. His services as an examiner were often called upon by universities and licensing bodies, and he acted on many occasions as visitor on behalf of the General Medical Council. In 1886 he was vice-president of the Mathematical and Physical Section of the British Association.

In 1907 another phase of his career opened, when he was appointed Principal and Vice-Chancellor of the Uni-

versity of Glasgow. He held this post with memorable dignity and efficiency for twenty-two years. Combined with eminence in arts and science and deep and varied scholarship, Donald MacAlister had great business aptitude and capacity for organization. During his tenure of office as Principal at Gilmorehill he saw the foundation of many new chairs and lectureships, among them being the professorships of obstetrics and gynaecology, surgery, medicine, and pathology at Glasgow Royal Infirmary; and at the University the chairs of Scottish history and literature, French, German, bacteriology, organic chemistry, mercantile law, and applied physics. Many new buildings also arose in the university quarter during his Principalship, notably the fine war memorial chapel. When he resigned

office in 1929 he was elected Chancellor of the University, a fitting recognition of fifty-five years' unbroken record of brilliant academic achievement. From 1908 until last year he continued to be a member of the General Medical Council, representing Glasgow University; in 1905 he had succeeded Sir William Turner of Edinburgh as President of that body. The whole period of his service on the Council thus extended over forty-four years.

Merely to enumerate the other public positions MacAlister held would prove wearisome, and a few only must suffice; thus, he had been at one time or another chairman of the Commission on Belfast University, member of the Royal Commission on the Civil Service, chairman of the Medical Consultative Council of the Scottish Board of Health, chairman of the British Pharmacopoeia Committee for many years, chairman of the Universities Bureau of the British Empire, honorary president of the International Congress of Hygiene at Madrid in 1898, and doyen of the

University Mission to France in 1919. He had been honoured by many universities: D.C.L. of Durham, LL.D. of Toronto, McGill, Aberdeen, Glasgow, St. Andrews, Liverpool, Belfast, Dublin, Wales, and Birmingham; D.Sc. of Bristol; and D.Phil. of Athens. He was also corresponding or honorary member of many learned societies at home and abroad, and an honorary Freeman of the City of Glasgow. In 1908 he was created K.C.B., and received a baronetcy in 1924; he was also a Commander of the Legion of Honour and a Cavalier of the Order of the Crown of Italy.

Sir Donald MacAlister had a long list of publications, medical and other, to his name, including a translation of Ziegler's *Pathological Anatomy*. A master of tongues, he spoke no fewer than fourteen languages with fluency;

[Russell, London]

Donald MacAlister

once at a Scottish dinner he replied to a toast in seven languages, including Japanese and a dialect of Chinese. His command of the Romany speech was recognized in 1915 by election as president of the Gipsy Lore Society. It was said that no distinguished foreign visitor ever went to Glasgow University but the Principal could speak to him in his mother tongue. Another literary interest was the translation of poetical works into different languages, and his volume of verse, *Echoes*, published first in 1907, went through three editions.

In former years Sir Donald MacAlister took an active part in the scientific work of the British Medical Association; he was vice-president of the Section of Pharmacology and Therapeutics at the Annual Meeting in London in 1895, and president of the Section of Therapeutics at the Toronto meeting in 1906. He was a prominent figure at the Annual Meeting in Glasgow in 1922, and, as Vice-Chancellor, presided with impressive eloquence at the honorary degree ceremony in the Bute Hall. Long before that he had served at headquarters on an Editorial Committee appointed to "co-operate with" the masterful Editor, Ernest Hart, in supervising the contents of the *British Medical Journal*. Occasionally the committee felt obliged to question or veto some of Mr. Hart's proposals, though not always with success. Sir Donald recalled in these columns many years later how "Dawson Williams as Assistant Editor attended our weekly meetings and took part in its proceedings tactfully, but always with effect. I learned then, what I realized more fully afterwards, how sure and wise was his handling of men and affairs."

He married in 1895 Edith, daughter of the late Professor Alexander Macalister, the Cambridge anatomist. They had no children, and with his death the baronetcy becomes extinct.

We are indebted to Sir NORMAN WALKER for the following appreciation of his predecessor in the presidential chair of the General Medical Council:

It is interesting to speculate on what would have been Donald MacAlister's career had he gone to Balliol, where he would have come under the influence of Jowett, and might have reached the Woolsack. We know that with the halo of the Senior Wranglership fast on his brow he came into contact with an eminent judge, who promised him his backing if he would apply himself to law. His brilliant undergraduate record in Cambridge seemed to mark him out for a mathematical career; he had serious thought of applying for the chair of mathematics in the university of which he later became Principal, and his first appointment was that of mathematical master at Harrow. This he only held for a year, for, unusual as was his approach to medicine, he always meant to be a doctor. The curriculum was shorter then, and his name appears on the *Medical Register* in April, 1881. His clinical work was done at St. Bartholomew's, and while a student there he held the post of lecturer on natural philosophy in the Medical School. He was an indefatigable worker, and he had to work. His father died in 1881, and he took on the responsibility of a widowed mother—a woman of strong character and intelligence, whose memory he ever held in reverence—and the education of his younger brothers and sisters. In the words of one of these latter, he was "a lovely big brother." After a period of post-graduate work in Leipzig he returned to Cambridge and put up his plate. His first published medical work was a translation of Ziegler's *Pathological Anatomy*, which went through three editions, and was one of the standard textbooks of the early 'eighties; but it was to pharmacology and therapeutics that he gave most attention, and the *British Pharmacopoeias* of 1898 and 1914 were largely his work. He was early on the staff of Addenbrooke's Hospital, was senior tutor at St. John's and Linacre Lecturer of Physic,

and practised as a consulting physician in Cambridge and the surrounding country.

But it was in "affairs" that he attained his highest distinction. He had a marvellous, almost uncanny, memory. He kept very few of the letters he received, and still fewer of the replies he wrote to them, always confident that he could remember both; he could tell in what volume and on what page any decision of the General Medical Council was recorded. Sir Donald's introduction to public affairs came in 1889, when, at the age of 35, having been eight years on the *Medical Register*, he stood for the representation of the University of Cambridge on the General Medical Council, the other candidate being the Regius Professor (Latham). The voting was 194 to 140. There are many different methods of election to membership of the Council; in Cambridge it was *more burgensium* by all the electors on the Roll, and in 1889 the number of doctors would not be great. It was to his zeal for university reform that Donald owed his election. He and Sir William Selby Church, representing Oxford, were introduced to the Council on the same day (November 26th, 1889) by Sir Dyce Duckworth. When he became Principal of the University of Glasgow in 1907 Cambridge invited him to complete the term for which he had been appointed as their representative. On the death of Sir Thomson McCall Anderson in 1908 Sir Donald was appointed representative of the University of Glasgow, and resigned his Cambridge seat.

What he did for the General Medical Council it would require a volume to tell. During his forty-four years of membership, of which twenty-seven were in the president's chair, he laboured unceasingly to make the Council a more and more efficient agency for carrying out the duties laid on it by the Medical Acts, and under his guidance the session grew more and more businesslike. He would have been the last to claim credit for it, but it is the fact that the financial stability of the Council markedly increased under his guidance. His capacity as chairman of a commission or committee is testified to by the number of such appointments he held. As a rule he occupied the chair in the sense conveyed by the name given to the chairman of the Ecclesiastical Court in Scotland—that of Moderator: one who reconciles the perhaps divergent views of a meeting. But when occasion arose he could be very stern, and had a disconcerting prescience of what some of the contestants were going to think ten minutes later. Though he lived for the greater part of his life in England his heart was rooted in the Highlands, and he was happiest when spending his vacation on the shores of Loch Fyne, surrounded like a Highland chief by members of his clan. His knowledge of languages was wonderful, but he used to say jocularly that the acquisition of any language was easy when one began with Gaelic. He was a devoted son of the Church of his fathers, and St. Columba's, Cambridge, abounds in records of the works of the MacAlisters. He married his "Highland" cousin, Edith, daughter of Alexander Macalister, professor of anatomy in Cambridge (formerly of Dublin), and to her, a real helpmate, the public is indebted more than it knows for the work Sir Donald, in spite of frail health, was able to do in the last twenty years.

An interesting account of the MacAlisters of Tarbert is appended to the full memoir published in the *Glasgow Herald* of January 16th, and in a tribute to Sir Donald MacAlister's notable services to the University and City of Glasgow our contemporary says:

It is, indeed, not as Chancellor but as Principal that he will be mourned to-day, for the unprecedented compliment of the higher dignity was conferred upon him, just over four years ago, as a token of the grateful regard in which his illustrious

services as executive head of the University were held by its graduates. In the twenty-two years during which he adorned that office the University went from strength to strength, and in that long record of development the personality of Sir Donald MacAlister was an important factor. The changes made in organization and curriculum bore the impress of the mind of a wise man, rich in experience and fertile in resources. The munificent benefactions made by Glasgow citizens towards the equipment of the University were an indication of general confidence in a leadership which would ensure that the best use would be made of these endowments. The reputation of the University in the outside world was enhanced by the circumstance that its presiding officer was a man of high and varied gifts, familiar with the conduct of affairs, who served the State in many capacities, and never without distinction and success.

JOHN BOWRING LAWFORD, M.D., C.M., LL.D., F.R.C.S.

Consulting Ophthalmic Surgeon to St. Thomas's Hospital

Through the death, on January 3rd at his home in Ashstead in his seventy-sixth year, of Mr. J. B. Lawford, ophthalmology has sustained a heavy loss. One of the few ophthalmologists with a personal recollection of Bowman, and an early pupil of Nettleship, he had during many years of his long life occupied one of the foremost positions in British ophthalmology.

Born in Montreal in 1858, he was already a graduate of McGill University when, at the age of 21, he came to this country and joined St. Thomas's Hospital. To his university degrees he soon added the conjoint diplomas of this country, and in 1885 he became a Fellow of the Royal College of Surgeons. In these early years the attraction of ophthalmology was already evident; he

became the clinical assistant at St. Thomas's of Edward Nettleship, whose devoted admirer he remained throughout his life. After holding the posts of assistant house-physician at St. Thomas's and resident clinical assistant at Bethlem Royal Hospital, he was appointed house-surgeon at Moorfields Eye Hospital in 1883, and in the following year became curator and pathologist at the same institution. Here it was that he first found the opportunity for original observation and research, and began the task, carried on for so many years, of adding to ophthalmic knowledge and literature. In 1886 he was appointed assistant ophthalmic surgeon at St. Thomas's, and four years later became assistant surgeon at Moorfields, attaining the status of full surgeon at both hospitals in 1895. At Moorfields he was for many years senior surgeon, and subsequently consulting surgeon. At St. Thomas's from 1891 until the date of his retirement in 1915, when he became consulting ophthalmic surgeon, he was lecturer in ophthalmology.

Owing to Lawford's wide knowledge of ophthalmology and of men and affairs, his sound judgement, and transparent honesty, it was natural that his counsel should be in great demand as a consultant in his specialty, and in the guidance of all undertakings in any way connected with it. In addition to his hospital appointments he filled the office of honorary secretary and president of the Ophthalmological Society of the United Kingdom, vice-president of the Ophthalmological Section of the Royal Society of Medicine, editor of the *Ophthalmic Review*, chairman of the Editorial Committee, and later managing

director, of the *British Journal of Ophthalmology*, and president of the Council of British Ophthalmologists. At the time of his death he was ophthalmic surgeon on the Medical Appeal Board of the Royal Navy, a post he had held for many years, and a member of the Preventive of Blindness Committee, in the work of which he took a very active part.

Throughout his life he was an indefatigable contributor to ophthalmic literature. His work, published in the various ophthalmological periodicals, covers a wide range, the contributions to the *Transactions of the Ophthalmological Society* alone numbering not far short of a hundred, and dealing with a great variety of subjects. He was the author of articles in Tuke's *Dictionary of Psychological Medicine* on "Pupil Reactions" and "Eye Symptoms in Insanity"; "Diseases of the Orbit" in the *Encyclopaedia Medica*; and "Ocular Lesions in Disorders of Secretory and Excretory Organs" in Norris and Oliver's *System of Diseases of the Eye*. He also did an immense amount of work in reviewing foreign literature for the *British Journal of Ophthalmology*, work which was continued to within a few days of his death. The work of the British Council of Ophthalmologists during his presidency included the arrangements for a deputation to the Ministry of Health on the subject of institutional treatment for children suffering from eye diseases.

Lawford was imbued with an exceptionally strong sense of duty, which ensured a willing response to the many calls for his services in an official capacity, and was evident in the punctilious care given to every detail of any work for which he was responsible. Yet, in spite of the heavy demands on his time which this involved, there was never any appearance of hurry or loss of equanimity, and to patients and subordinates alike there was invariably accorded a kindly and courteous consideration and attention. In his hours of leisure he was a genial companion and host, and at such times occasional sallies of playful humour would endow his customarily rather sedate demeanour with a peculiar charm. He was a highly accomplished operator, using either hand with equal facility, and seldom failing to attain precisely his objective. Lawford's distinguished services to ophthalmology were recognized outside the British Isles by his being made the recipient of the honorary membership of the Société Française d'Ophthalmologie, honorary fellowship of the American Academy of Ophthalmology and Otolaryngology, and the degree of Hon. LL.D. of McGill University.

He never married, and for many years lived with his mother and sisters, two of whom survive him.

W. W. HERBERT, M.D., C.M. Llangollen, North Wales

We regret to announce the death on January 3rd of Dr. William Whittington Herbert, at his residence in Llangollen, at the age of 73. Dr. Herbert was trained in the University of Edinburgh, where he graduated M.B., C.M. in 1882, and proceeded M.D. in 1886. Psychiatry attracted him from the start of his medical career, and soon after graduation he was appointed medical officer to the North Wales Counties Asylum at Denbigh. For thirty years he continued to serve this institution, retiring in 1912. He had for some years been deputy superintendent, and had also held the post of medical superintendent of Fisherton House Asylum, Salisbury. He was medical officer in charge of prisoners of war at the Queensferry and Lancaster internment camps, and after the war was appointed neurological specialist to the Ministry of Pensions for the North Wales area. The latter part of

his life was devoted to public duties of different kinds. He was a member of the Denbighshire County Council, and as chairman of its mental deficiency committee was largely responsible for the acquisition of an institution for the care of mental defectives. He was also J.P. for the county, and a member of the Corwen board of guardians. He was a strong supporter of eugenics and an advocate of sterilization of the chronic mentally unfit. Dr. Herbert had been a member of the British Medical Association since 1886, and in 1894 contributed an article to the *British Medical Journal* on forced feeding of the insane. A genial companion, ardent sportsman, and a keen fighter for the ideals he held, he had many friends. The Archbishop of Wales officiated at his funeral on January 6th, which was attended by a large gathering.

C. H. writes: There is something rather tragic in the death of Dr. Herbert just at a moment when the report of the Departmental Committee of the Ministry of Health on sterilization is about to appear, for few people in the country worked more effectively and with greater enthusiasm in their own locality to secure recognition of the biological aspects underlying mental pathology. Exactly nine years ago Dr. Herbert, who had then already retired from the Denbigh County Hospital, began to correspond with eugenicists in London on the practical possibilities of offering some method for family limitation to patients leaving the asylum cured, whose disease was of a familial type. As a member of the Denbigh County Council and chairman for some time of the committee dealing with mental defectives for that area, he went on ceaselessly with education and persuasion, and had the satisfaction of securing results for his own county in 1931 in favour of birth control provision (for suitable cases) and of recommendation of sterilization to patients leaving the mental hospital.

WILLIAM J. MAGUIRE, M.D., F.R.C.P.I.

Late Medical Commissioner, National Health Commission,
Ireland

The death took place recently, at his residence at Ardeevin, Highfield Road, Dublin, of Dr. William J. Maguire. He was the second son of the late William Maguire of Tudor Park, Hollywood, County Down, and received his early education at St. Malachy's and Owen's Colleges, Belfast, and at St. Joseph's Seminary, Dublin. He took his B.A. at the Royal University in 1892, and his M.B., B.Ch., B.A.O. in 1894, proceeding M.D. in 1907. He became a Member of the Royal College of Physicians of Ireland in 1908, and was elected a Fellow in the same year. He practised in Belfast from the time he qualified in 1894 until 1912, when he was appointed medical commissioner of the National Health Insurance Commission, a post which he held until his retirement last year under the age regulation of 65. Before his appointment as medical commissioner he held the posts of senior visiting physician to the Mater Infirmorum Hospital, Belfast; clinical lecturer and examiner in medicine, Queen's University, Belfast; and extern examiner in the National University. Dr. Maguire was very popular with the medical profession, especially when matters settled down after the certification dispute, and he always took care that medical men received fair play from the approved societies. He contributed a paper on "Early Immunization as a Preventive Measure against Tuberculosis" at the Royal Institute of Public Health Congress, Dublin, 1928. Dr. Maguire is survived by his widow, his son, Dr. Joseph Ballantyne Maguire, who is medical officer on the White Star liner *Britannic*, and two daughters, one of whom is Dr. Wilhelmina Colquhoun Maguire, Camberwell House Mental Hospital, London.

JOHN STEWART AND IRVING CAMERON.

Dr. ALFRED COX writes:

I should be wanting in my duty if I did not pay a pious tribute to the memory of the two eminent Canadians whose obituaries you have recently published. The first time I was in Canada I did not meet John Stewart, but I heard of him all the way across from Quebec to Winnipeg, and what I heard made me very anxious to meet him. It was evident that he was to the Canadian profession an object of peculiar pride, affection, and almost reverence; he was the grand old man of the medical profession. It must be rare for a man in a remote corner of a vast country to have a national reputation of this kind. I met him at Edinburgh, and again at our Annual Meeting at Winnipeg, and then I understood. The natural dignity, unaffected kindness, and shining integrity of the man made him irresistible. One felt that he was fundamentally sincere and great—a feeling one gets but rarely in one's contacts with the world, but to be treasured when it is felt. His death leaves a blank in Canada which nobody can fill, and I can faintly realize what it must mean to the profession in his own Nova Scotia, where he was for so long the outstanding example of a good man and a good doctor.

As for Professor Irving Cameron, I should like to say, because I know he would have liked it to be said, how he enjoyed his annual visits to this country. He always paid an early visit to the B.M.A. "to pay his respects," as he said, "to the heads of the leading medical body of the leading country in the world," by which he meant the Editor and myself. I remember him on several occasions at 429, Strand. When we moved to Tavistock Square he always commenced by saying: "I'm a very old man, I've come annually for so many years, and I expect this will be my last visit." It was a standing joke between us that even when he had disappeared from this world the force of habit would impel his ghost to make the usual annual visit. He was, as Professor Grey Turner says, a tremendous loyalist to the Imperial idea, and loved to think himself, as indeed he was, an unofficial but none the less useful and appreciated link between the Canadian profession and the B.M.A.

With the death on December 31st, 1933, of Dr. ALEXANDER MCNEILL D'EVELYN of Ballymena there passed one who had achieved distinction in many spheres of life and had won a great respect and affection. His medical education had been received at Trinity College, Dublin, where he graduated M.B., B.Ch. in 1886, and obtained the diploma L.M. at the Rotunda Hospital. Four years later he proceeded M.D. At first he held an appointment as medical officer to a steamship company, and travelled much in the Far East. He settled in Ballymena forty-four years ago, and soon built up a large practice. He was for many years medical officer to the Braidwater Spinning Company. From the establishment of the Ballymena Cottage Hospital he devoted himself very actively to its interests, and for a long time was secretary of the medical staff. He invariably submitted the medical report of the institution at its annual meetings on December 11th, and this he did at its last meeting in 1933, twenty days before his unexpected death within its walls. He was a medical visitor in lunacy. Raised to the magisterial bench more than thirty years ago, he took great interest in petty sessions work, where his wide experience and humanity won him general esteem. Always a student of antiquarian research, he possessed a very fine collection of archaeological specimens. He was a fellow of the Royal Society of Antiquarians of Ireland and a member of the Belfast Naturalists' Field Club. A keen Mason, Dr. D'Evelyn held rank in the Provincial Grand Lodge of Antrim, was Past Master of his Lodge, a member of R.A.C. and Preceptor, and chairman of the local masonic hall committee. He was active in promoting the erection of the present fine masonic temple in Ballymena. One of his chief recreations was fishing, and he spent many holidays fishing the lakes and rivers of Western Ireland, combining

this with hunting for antiquities. He was chairman of the Mid-Antrim Anglers' Association, and did much for this society and its work of pisciculture. Dr. D'Evelyn was unmarried. He had been a member of the British Medical Association since 1888.

Dr. PERCY ROBERT MANDER, whose death at the age of 74 took place on January 8th, received his medical education at Westminster Hospital. He obtained an exhibition in anatomy and physiology in 1880, a scholarship in anatomy and physiology in 1881, a prize in clinical medicine in 1883, and was senior house-surgeon in 1886. He qualified L.S.A. Lond. in 1883, M.R.C.S. Eng. in 1884, and L.R.C.P. Lond. in 1886. In 1901 he took the M.D. degree of Durham University, and was a member of the British Medical Association for many years. Mander joined the Prison Service in 1892 and served for seven years at Dartmoor Prison, and later at Wandsworth, Stafford, Portland, Pentonville, and Parkhurst Prisons. He retired in 1923 to the Isle of Wight and later removed to Ealing. He was a man of high ideals, a staunch and loyal colleague, and combined firmness of purpose with modesty, moral courage, wide human sympathy, and understanding. During the thirty-one years in which he served the public as a prison medical officer he came into contact with a vast number of the criminal population, but his faith in human nature remained unshaken. The writer of these notes worked with him for a few weeks in the summer of 1899 at Dartmoor Prison and received at the time wise counsel which is still remembered. Mander was a particularly lovable man and was devoted to his prison work. His loss severs a link with past prison medical practice, but he will ever be remembered with affection by those with whom he worked. W. N. E.

The following well-known foreign medical men have recently died: Dr. GIUSEPPE PORTICUOTTI, an eminent psychiatrist of Genoa; Dr. PAUL RICHER, member of the Institut de France and Académie de Médecine, founder of the Nouvelle Iconographie de la Salpêtrière and collaborator of Charcot, aged 84; Dr. JUST LUCAS-CHAMPIONNIÈRE, professor at the medical school at Hanoi, and director of the *Journal de Médecine et de Chirurgie Pratiques*; and Dr. JULIO IRIBARNE, formerly dean of the Buenos Aires Faculty of Medicine, from injuries received in a motor accident.

The Services

DEATHS IN THE SERVICES

Colonel Roger Kirkpatrick, C.B., C.M.G., late R.A.M.C., died at Knockhill, Ecclefechan, on December 20th, 1933, aged 74. He was born at Bangalore on June 19th, 1859, and was educated at Edinburgh University, where he graduated M.B., C.M. in 1881, and as M.D. in 1894, also taking the M.R.C.S. in 1881. Entering the Army as surgeon on July 29th, 1882, he became lieutenant-colonel after twenty years' service, and colonel on May 21st, 1912, retiring on December 26th, 1917. He had a long list of war service: Burma, 1886-8 (medal with two clasps); North-West Frontier of India, 1897-8, Buner campaign and attack and capture of the Tanga Pass, medal with clasp, and Tirah, 1897-8 (clasp); South Africa, 1899-1902, relief of Ladysmith, including actions of Colenso and Tugla Heights, operations in Natal, and afterwards as P.M.O. of a general hospital, mentioned in dispatches in the *London Gazette* of February 8th and September 14th, 1901 (Queen's medal with four clasps, and King's medal with two clasps, and C.M.G.); war of 1914-18, as D.D.M.S. (mentioned in dispatches in *London Gazette* of January 1st, 1916, and May 29th, 1917, and received the C.B. in 1917).

Lieut.-Colonel Nicholas Percell O'Gorman Lalor, Madras Medical Service (ret.), died in London on December 26th, 1933, aged 63. He was born in Dublin on January 1st, 1869, the son of Nicholas James Lalor, merchant, Dublin, and graduated M.B., B.Ch. in the Royal University of Ireland in 1896. Entering the I.M.S. as surgeon lieutenant on January 29th, 1896, he became lieutenant colonel on July 29th, 1915, and retired on July 25th, 1918. He served on the North-West Frontier of India in the Mohmand campaign in

1897-8 (medal with clasp); and in China, 1900 (medal). He was the author of *Hospital and Dispensary Code for Sub-Assistant Surgeons*, 1911, and *The Campaign Against Malaria in Italy*, 1912.

Universities and Colleges

UNIVERSITY OF OXFORD

The electors to Dr. Lee's Professorship of Human Anatomy have appointed to the chair Mr. Wilfrid E. Le Gros Clark, D.Sc., F.R.C.S., now Professor of Anatomy at St. Thomas's Hospital Medical School (University of London), and formerly Professor of Anatomy at St. Bartholomew's.

UNIVERSITY OF LONDON

The following have been recognized as teachers in the subjects indicated. *St. Bartholomew's Hospital Medical School*: Dr. W. M. Levitt (radiology). *London Hospital Medical College*: Mr. C. Donald (surgery). *Dr. Horace Evans (medicine)*. *Charing Cross Hospital Medical School*: Mr. R. A. Fitzsimons (surgery). *St. Mary's Hospital Medical School*: Dr. G. R. Phillips (anaesthetics). *Royal Dental Hospital of London*: Mr. L. E. Claremont, Mr. C. Bowdler, Mr. S. A. Kiddett, and Mr. H. Stobie (dental surgery).

The regulations relating to exemptions in respect of the course for the first examination for medical degrees for internal students (Red Book, 1933 4, pp. 200-1) have been amended as follows:

- By the deletion of the following words from Section 2 (v) provided that they have completed the required courses of study.
- By the addition of the following section. (vi) Candidates who have passed the higher school examination of the University of London in accordance with the prescribed conditions for exemption may be exempted from the first examination for medical degrees in whole or in part.

The Senate offer seven post-graduate studentships of the value of £150 per annum open to internal and external graduates of the University in any Faculty. A graduate who has completed his twenty-fifth year on or before June 1st in the year of award will not be eligible. The studentships will be tenable for one year only in the first instance, but may be renewed for a second year at the discretion of the Scholarships Committee. Applications for renewal will be considered by the Scholarships Committee simultaneously with applications for first awards. Applications must be made on a prescribed form, which may be obtained from the Principal, and must be accompanied by two testimonials and the names of not more than two persons to whom reference may be made. Selected candidates will be required to attend for an interview with the committee. Candidates must submit a scheme of work for approval. The awards will be made in June, and applications must reach the Principal not later than May 1st.

Two University post-graduate travelling studentships, each of the value of £275 for one year, will be awarded annually if candidates of sufficient merit shall present themselves. The studentships are open to internal and external graduates of the University in any Faculty. A graduate who has completed his twenty-eighth year on or before June 1st in the year of award will not be eligible. If a studentship is not awarded in any year, an additional studentship may be awarded in a subsequent year. Candidates will be required, if elected, to spend the year of tenure abroad, and must submit a scheme of work for approval. Applications must be made on a prescribed form, which may be obtained from the Principal, and must be accompanied by two testimonials and the names of two persons to whom reference may be made; selected candidates will be required to attend for an interview with the committee. The awards will be made in June, and applications must reach the Principal not later than May 1st.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

Professor W. W. Jameson, dean of the London School of Hygiene and Tropical Medicine, arrived in Colombo on January 9th. He is touring Ceylon and India with representatives of the Rockefeller Foundation. In view of the amalgamation of the Ross Institute with the London School of Hygiene and Tropical Medicine, Professor Jameson will, before returning home, visit some of the Ross Institute research centres in Assam and Bengal, and afterwards proceed to Malaya. During his absence Professor R. T. Leiper, F.R.S., has been appointed acting dean of the London School. Professor Jameson is expected back in London in April.

Professor J. Gordon Thomson, director of the department of protozoology, is leaving London on January 31st, and will travel by air to South Africa. He will proceed to East

Africa, where he will spend six months doing special research work on malaria and sleeping sickness, with special reference to immunity.

UNIVERSITY OF LEEDS

On January 12th Sir Frederick Gowland Hopkins, President of the Royal Society, opened the new building of the department of chemistry. Professor R. W. Whytlaw Gray, who is head of the whole department, will be in charge of the inorganic section, Professor H. M. Dawson of the physical chemistry section, and Professor F. Challenger of the organic floor.

NATIONAL UNIVERSITY OF IRELAND

At a meeting of the Senate on January 11th, with the pro-vice-chancellor, Dr. Denis J. Coffey, in the chair, the reports of the examiners upon the medical and dental examinations, December, 1933, were considered, and passes, honours, etc., awarded. It was decided that a supplemental first university examination in medicine should be held in the three constituent colleges during the spring, the latest date for entry thereto to be February 1st.

The Senate appointed the following representatives: Professor T. Walsh, M.D., Royal Sanitary Institute Congress, Bristol; Professor W. D. O'Kelly, M.D., National Association for Prevention of Tuberculosis Conference, London.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly Council meeting was held on January 11th, when the President, Sir Holburt Waring, was in the chair.

Dr. John Beattie was admitted to office as conservator of the museum and director of research.

A diploma of Fellowship was granted to T. T. Stamm of Guy's Hospital.

The Hallett Prize for Anatomy and Physiology was awarded to Ananda Nimalasuria of Ceylon Medical College and King's College, London.

The following diplomas in special subjects were granted jointly with the Royal College of Physicians:

TROPICAL MEDICINE AND HYGIENE.—G. H. Coomay, P. W. Godfrey, G. M. Raby, B. H. Rassam, R. du T. van der Merwe.

PSYCHOLOGICAL MEDICINE.—J. S. Allen, C. C. Beresford, P. M. Crowe, Cicely L. Hingston, J. H. R. Laptain, J. K. Marshall, T. C. St. C. Morton, W. C. M. Scott, J. A. Shaby, E. T. O. Slater.

LARYNGOLOGY AND OTOTOLOGY.—W. G. Bridgman, I. C. Fraser, K. George, T. P. Gill, A. C. Goodwin, M. Gordon, H. G. Grieve, R. H. Milnas, P. L. O'Neill, I. M. Kutherford, I. B. Senjit, A. D. Smith.

MEDICAL RADIOLOGY.—J. B. Douglas, R. S. Harrison, J. E. Wilson Lee.

Medical News

The annual dinner of the Hunterian Society of London will be held at the May Fair Hotel, Berkeley Street, W., on Thursday, February 8th.

The thirteenth annual dinner of the Society of Radiographers will be held at the Restaurant Frascati, Oxford Street, on Saturday, February 10th, at 7.30 p.m., with the president, Dr. L. A. Rowden, in the chair.

On Friday, January 26th, at 8.45 p.m., at the Princess Elizabeth of York Children's Hospital, Glamis Road, Shadwell, E., Mrs. Lilian Lindsay, L.D.S., will give a lantern lecture on "The Influence of the Sun upon the Teeth—Ancient and Modern." Sir Frank Colyer will preside.

Meetings of the Fever Hospital Medical Service Group and the Maternity and Child Welfare Group will be held at the house of the Society of Medical Officers of Health, 1, Upper Montague Street, W.C., on Friday, January 26th. At the first meeting, at 4.30 p.m., Dr. W. Mair will read a paper on "Varieties of *Corynebacterium diphtheriae*," and at the second meeting, at 8.30 p.m., there will be a discussion on "Diet for the Pre-school Child," to be opened by Professor V. H. Mottam.

All communications for the Ross Institute and Hospital for Tropical Diseases, Putney Heath, S.W.15, should now be addressed to the Ross Institute of Tropical Hygiene, Kippel Street, Gower Street, W.C.1.

The Minister of Health announces that, under arrangements consequent upon the retirement from the public service of Dame Janet Campbell, D.B.E., M.D., M.S., as from December 31st last, and of Sir George Buchanan, C.B., M.D., F.R.C.P., as from February 18th, 1934, Dr. Jane H. Turnbull, C.B.E., will be in charge of the Maternity and Child Welfare Division of the Medical Staff of the Ministry, and Dr. J. M. Hamill, O.B.E., will act as senior medical officer in charge of the Foods Division of that staff.

The fifty-first post-graduate course of the medical faculty of Vienna will be held during the fortnight February 12th to 25th, the subject being diseases of the intestines and metabolism, with reference also to the related pathological and surgical aspects. It will be followed by a week of group instruction devoted to clinical study. Further information may be obtained from Dr. A. Kronfeld, Porzellangasse 22, Vienna IX.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the second lecture-demonstration by Dr. Clark-Kennedy will take place at 11, Chandos Street, W., on January 23rd, at 2.30 p.m.; subject, "Nervous Dyspepsia." The third will be on January 30th; subject, "Organic Dyspepsia." There will be a course in dermatology at St. John's Hospital, Leicester Square, from January 29th to February 24th. A week's course in neurology, especially suitable for the general practitioner, will be given at the West End Hospital for Nervous Diseases, February 5th to 10th, and will occupy the whole of each day. A course in gynaecology, occupying mornings and/or afternoons, will be given at the Chelsea Hospital for Women, from February 5th to 17th. Six demonstrations on the interpretation of pyelograms will be given by Dr. Mather Cordner at 8 p.m. on Tuesdays and Fridays from February 13th to March 2nd; they will include radiographic technique, radiological anatomy and physiology of urinary tract, obstructive conditions and inflammatory lesions, renal and uterine stones, renal tumours, etc.

The December issue of *The Human Factor*, the monthly organ of the National Institute of Industrial Psychology, is devoted to the annual report and statement of accounts for the period from January 1st to September 30th, 1933. The report is the thirteenth issued by the council of the Institute, and on this occasion a change has been made, the year for review terminating henceforth on September 30th instead of on December 31st. There has been a considerable extension of the work in connexion with vocational guidance cases, and school teachers in Birmingham and Willesden have received instruction in vocational examination. This training has also been imparted to foreign psychologists, and courses of lectures have been delivered in London and elsewhere. Investigations have continued on an undiminished scale at factories and offices with a view to improving their efficiency. Research work is being pushed, but the main endowment for this—namely, the Rockefeller annual grant, is diminishing in amount, and will terminate in 1936. Included in this research work last year were investigations of rhythm in occupational movements, the nature and measurement of the mental abilities involved in factory assembly operations, tests for motor drivers, a study of colour discrimination, and improvement of the intelligence tests.

A new volume in the Cambridge Comparative Physiology Series, entitled *The Elements of Experimental Embryology*, by Professor J. S. Huxley and Dr. C. R. de Beer, will be published by the Cambridge University Press in February.

The issue of *Nederlandsch Tijdschrift voor Geneeskunde* for January 6th contains an instructive article by Professor J. A. J. Barge of Leyden on medical education at the University of Leyden in the eighteenth century, illustrated by portraits of the leading professors.

A new chair for racial hygiene has been founded in Berlin, with Professor Fritz Lenz of Munich as its first occupant. Professor Lenz has also been appointed departmental director for racial hygiene and eugenics at the Kaiser Wilhelm Institute for Anthropology in Berlin.

The forthcoming number of the *Journal of Neurology and Psychopathology* will include a full report of a conference of the programme-executive committee for the second International Neurological Congress. The conference, held in London last autumn, was attended by delegates from fourteen countries, who nominated officers for the congress as follows: honorary president, Dr. B. Sachs (New York); president, Sir Charles Sherrington (Oxford); deputy-president, Dr. Gordon M. Holmes (London), together with sixteen vice-presidents. Dr. S. A. Kinnier Wilson (14, Harley Street, W.1) was appointed secretary-general, Dr. M. Critchley and Dr. E. A. Carmichael, assistant secretaries, Dr. Anthony Feiling, treasurer, and Dr. Gordon Holmes, editor of transactions. It was decided that the congress should take place in London from Monday, July 29th, to Friday, August 2nd, 1935. The following four subjects were chosen for discussion at the morning sessions: (1) the epilepsies—their aetiology, pathogenesis, and treatment; (2) physiology and pathology of the cerebro-spinal fluid; (3) functions of the frontal lobe; and (4) the hypothalamus and the central representation of the autonomic system.

The Departmental Committee on the Composition and Description of Food, which is considering whether it is desirable that the law should be altered so as to enable definitions or standards to be prescribed, held meetings last week. Evidence was given on behalf of the Society of Chemical Industry by Dr. L. H. Lampitt, chairman of the Food Group of the Society, Dr. H. E. Cox, and Professor Raistrick, and by witnesses appearing for various trade associations. Evidence was also given by Mr. T. Macara regarding infants' and invalids' foods on behalf of the Food Manufacturers' Federation, and by the town clerk of Chester for the Association of Municipal Corporations. The meetings were presided over by Sir Frederick Munn, the secretary of the committee is Mr. W. J. Peete, of the Ministry of Health, to whom any communication should be addressed.

E. P. Poulton of London, Hernando of Madrid, Drs. of Bern, Sanarelli of Rome, Pende of Genoa, J. J. Bursi of Baltimore, Glassner of Vienna, and Vogelinus of Copenhagen were recently elected honorary members of the Société de Thérapie de Paris.

Dr. Gilbert Orme has been awarded the Order of Mercy for special services rendered to the League of Mercy.

The following medical promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem are announced in the *London Gazette* of January 2nd: as Commanders, Dr. W. H. Carse, Major F. Howard Humphris, and Colonel Sir Richard A. Needham, C.I.E., D.S.O.; as Officers, Lieut.-Colonel A. D. Stewart, I.M.S., Mr. J. Johnston Abraham, C.B.E., D.S.O., Major H. A. Sandilford, M.C., R.A.M.C., and Dr. W. H. Kauntze, M.B.E.; as Serving Brothers, Dr. H. G. Hankins, Mr. C. A. Parker, Dr. F. H. Flaek, Dr. J. W. Graham, Dr. J. M. Postlethwaite, Dr. P. McRitchie, Dr. F. E. Bendix, Dr. H. F. Percival, O.B.E., Dr. W. E. Fairweather, and Lieut.-Colonel C. H. James, C.I.E.

Mr. T. H. Bickerton, F.R.C.S., of Liverpool, who died on November 23rd, 1933, aged 76, left estate of the gross value of £435,229.

Professor Rille, director of the clinic for skin diseases at Leipzig, has been elected an honorary member of the Turkish Dermatological Society, and Dr. Robert Rösle, professor of pathology at Berlin, an honorary member of the Medical Society of Vienna.

Dr. von Deschwanden of Lucerne has been elected president of the International Hospital Association in place of Dr. René Sand, who has resigned. The presidency of honour has been offered to Prince Charles of Sweden.

Dr. Jose Maria Gutierrez Barrat has been appointed Director-General of Public Health in Spain.

Mr. Henry Thomas Baker of Bournemouth has given £10,000 and the income from shares valued at £15,000 to the extension fund of the King George Hospital, Ilford.

A modern leprosy hospital has recently been opened at Genoa.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Atology Westcat, London*.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcat, London*.

MEDICAL SECRETARY, *Medisecra Westcat, London*.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Baillius, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshagh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24261 Edinburgh).

QUERIES AND ANSWERS

Diabetic Paying Guest

Dr. G. E. CLANTON (Radnor Park Road, Folkestone) would be glad to hear from a London doctor who could recommend a family willing to take a diabetic lady, engaged in secretarial work in London, as a paying guest. It would be preferable if one of the members of the family is a diabetic, so that the difficulties of diet would be obviated.

Oysters, Calories, and Food Prices

Dr. EDWARD J. CROSS (St. Neots) writes: In the *Times* of October 4th, 1933, Professor E. C. Dodds is reported to have stated in his address at the Queen's Hall that a dozen oysters would yield 88 calories of energy. In the *British Medical Journal* of January 6th Professor J. A. Nixon states that half a dozen oysters contain 24 grams protein, 10 grams fat, and 12 grams carbohydrate. Surely this means that six oysters yield 234 calories. Can you please explain this to me, as I am very perplexed. Also Professor Nixon says that 1 lb. will buy 1 lb. of beef. I have to pay 1s. 6d. for 1 lb. of steak without bone or gristle. Five pints of milk in this vicinity cost 1s. 5d.

Chlorophyll and Crème de Menthe

Dr. G. M. FLEMING (Long Sutton, Lincs) writes. I cannot answer directly the query by Rear-Admiral Beadnell, and await with interest the replies of other readers. As a contribution towards the nature of green dyes in use, however, I tender my own researches. I recently received a sample of a green tonic which, I am satisfied, is a very effective preparation—so much so that I now use it regularly. As I wandered round Woolworth's the other day, speculating idly as to whether the green dye or the glycerophosphates were the more active ingredient, I perceived a bottle of green dye ostensibly purveyed for pigmenting puddings. The Woolworth liquid showed the following bands in moderate dilution: I, 6,500 to 7,000, strong. II, 5,900; weak. III, 3,900 to 4,800, very strong. Band III has a sharp cut-off. The width of Band II varies with the concentration. The bands shown by the green tonic are identical. On hydrolysing, Bands I and II disappear, but Band III remains very strong. The dye in both cases is probably the anhydride of the zinc salt of tetra-methyl-di-amido-triphenyl-carbinol. The absorption bands of chlorophyll are entirely different, and I doubt if this substance would withstand the ageing which we hope crème de menthe undergoes. I should be glad of an opinion as to the toxicity, if any, of the dye mentioned.

Income Tax

Tax on Interest Received

"Tintax" is a married man with an income of £700—all "unearned"—in 1932-3, of which £275 was war loan interest and £10 from deposit interest. His daughter is being educated at a university—her own income is under

£20—and there is a dependent relative who "receives relief of £10." What should the assessment be for 1933-4?

* The war loan interest can be taken at the actual 3½ per cent. rate received in 1933-4, and the position is as follows:

Assessable interest, £192 + £10	£202
Allowances: (1) Personal, £150		
(2) "Child," £50	£200
		£2

Tax payable at 2s. 6d. in the £ = 5s.

"Tintax" is entitled to have £175 of his income taxed at 2s. 6d., and, as the rest of his total income has presumably paid tax at 5s., he is entitled to a refund of £175 at 2s. 6d. = £21 17s. 6d., less the 5s. due—that is, £21 12s. 6d. net. The claim to dependent relative allowance will probably be refused, as £10 is presumably not sufficient to maintain the relative.

LETTERS, NOTES, ETC.

Meta Fuel Poisoning

ELMESAN (LONDON) LIMITED, referring to two instances of poisoning from taking "meta" fuel—metaldehyde—(CH₃CO)₂—by mouth, write: We feel that it is in the interests of all doctors, chemists, nurses, etc., that we should make known a little more about the treatment which should be administered in such cases. We therefore give details of the procedure recommended by Dr. Laszlo Wamoscher, associate professor at the Hygiene Institute, University of Berlin: (1) Immediate wash-outs of the stomach with large quantities of sodium bicarbonate solution. These should be repeated frequently and performed slowly for the first time, on account of the development of CO₂. (2) High colon wash-outs of the bowels with alkaline solutions. (3) Purgatives after washing out: Glauber's salts or castor-oil. No phenolphthalein or acids. (4) Large quantities of charcoal, preferably wood charcoal. (5) For the heart: caffeine, and, if necessary, strophanthin intravenously. (6) No narcotics, if possible. Against the cramps becoming too intensive: the sodium salt of veronal. (7) Intravenous injections of calcium (Sandoz) and, by all means, repeated intravenous injections of 30 to 40 per cent. glucose.

Eugenics and the Doctor

Mr. RONALD PRIME, M.R.C.V.S. (London, S.E.19), writes: I read with the greatest interest Lord Horder's address on the question of eugenics and the doctor in your issue of December 9th, 1933. In the veterinary profession, more than in any other, one has the opportunity of observing the signal success which has attended the adoption of strict scientific principles in the breeding of the domesticated animals. That similar results would follow if more careful consideration and scientific attention were given to human sexual selection and mating is indubitable. I do not, however, quite agree with Lord Horder when he states that in the minds of the great majority of people there is no reaction at all towards the practice of eugenics. This certainly does not seem to be the case with the younger generation to-day. As lecturer to large numbers of young men of all classes engaged in one of the chief industries of this country, I have been amazed by the sincere and eager desire of nearly all of them for knowledge of genetics and eugenics. The tragedy at present is that far too little is definitely known of these problems, and hence much earnest inquiry has to remain unanswered or be answered unsatisfactorily. Far more research into animal and human genetics is needed, followed by careful dissemination, by medical men and educationists, of the more salient results among the general public.

Air Ambulances

Group Captain W. TYRRELL, R.A.F.M.S., writes from Cairo: I was interested to read in the *Journal* of December 23rd, 1933 (p. 1171), your account of the meeting of the Royal Society of Medicine (United Services Section), when a paper on air ambulances, by Colonel E. M. Cowell, was read and discussed. As a matter of historical interest and accuracy I think it should be noted that the first occasion on which a British aircraft was specially designed and officially delegated to carry sick and wounded was during the first Royal Air Force punitive expedition in Somaliland, 1919-20, when a De Havilland 9, with a fuselage modified to carry one stretcher and attendant, was used, under desert warfare conditions, to evacuate cases from advanced aerodromes and aid posts to the base hospital. (Vide Report on the Health of the Royal Air Force for the year, 1920, vol. i, p. 58.)

James Bryce

Mr. CYRIL C. BARNARD, librarian, London School of Hygiene and Tropical Medicine, writes: A footnote to your Nova et Vetera item on page 1180 of the issue of December 23rd, 1933, states that "This *Lexikon* [namely, *Biographisches Lexikon der hervorragenden Ärzte aller Zeiten und Völker*] calls him 'James B. Bryce,' but in his writings Bryce always calls himself 'James Bryce.' The writer of the note and others may like to know that it is the irritating practice throughout the aforesaid *Lexikon* to insert after the Christian names the first letter of the surname, so that "James B." in this instance merely means James Bryce.

Members of the Royal College of Surgeons

Mr. JOHN GRIFFITH, M.R.C.S. (London, W.), writes: Again this year comes to pass the perennial refusal to allow Members on the executive board of the Royal College of Surgeons of England. Why put up with it? May I be allowed to point out a certain remedy? Let young Englishmen and South Welshmen cease to sit for the examinations of the Conjoint Board, which in my opinion will effectively take the starch out of the collars of these autocratic Fellows. There remain the provincial universities, with their degrees and superior status. The examinations of this board to the ordinary individual appear incomprehensible. Personally, I had worked too hard for its final examination; I was referred twice. The impression left on my mind is that the examination is like the curate's hair—patchy in places.

A Treatment of Cancer

Dr. MAX HONIGSBERGER (Stechford, Birmingham) writes: In your annotation (January 13th) on the cancer treatment originated by Professor Fichera of Milan one important point is not mentioned—namely, the relief of pain obtained by the treatment. In a recent case of inoperable carcinoma of the stomach, where pain was not allayed by the usual doses of morphine, the fourth injection of Fichera 365 (Bayer) gave almost complete relief, and this state was continued until death supervened some time later.

Insulin Prices

Burroughs Wellcome and Co. announce a reduction of 13th to 14th of "Wellcome" brand insulin, which are now as follows: "Wellcome" brand insulin, 20 units per c.c.m., 5 c.c.m. phials, 1s. 10d. each; 20 units per c.c.m., 10 c.c.m. phials, 3s. 6d. each; 40 units per c.c.m., 5 c.c.m. phials, 3s. 6d. each; 80 units per c.c.m., 5 c.c.m. phials, 6s. 9d. each. The price of "tabloid" hypodermic insulin hydrochloride (10 units) has also been reduced. Cartons containing ten products in one tube are quoted at 1s. 10d. per tube. These are London prices to the medical profession.

Wanted: A Skeleton

Miss M. FORRESTER-BROWN, M.S., M.D., visiting surgeon, Bath and Wessex Orthopaedic Hospital, writes. Would you accord me the courtesy of your columns to inquire whether any practitioner has a spare articulated skeleton which he would be willing to pass on to this hospital for the use of the nurses in their studies of anatomy and of bone and joint diseases. The institution is still an adolescent one, and its finances do not for some time permit of purchasing one at the ordinary market price; but yet it is a very desirable piece of equipment in an institution of this nature, as I realize when I have to lecture to the nurses on orthopaedics.

The Food Education Society (29, Gordon Square, W.C.1) has issued a little pamphlet, *Vegetable and Salad Dishes*, post free, 3d., which gives hints on how to lay out the money to the best advantage, and simple yet dainty and nourishing recipes. Quantities of twenty-five and upwards may be had at reduced rates.

Harrogate Corporation has just been granted a patent for enabling the "Nauheim" CO₂ bath treatment to be given more efficiently than hitherto at the bathing establishment.

Vacancies

Notifications of officers vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 48, 49, 50, 51, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 23.

A Paper

ON

BODILY DISEASES IN MENTAL DISORDERS

BY

ARTHUR J. HALL, M.A., M.D., D.Sc., F.R.C.P.

EMERITUS PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD;
CONSULTING PHYSICIAN, SHEFFIELD LOYAL HOSPITAL; VISITING
PHYSICIAN, SOUTH YORKSHIRE MENTAL HOSPITAL, AND
THE STATE INSTITUTION, BARSTON, NOTTS

Although for the sake of convenience it is customary to make a distinction between mental and bodily disorders, such separation of the two is physiologically unsound. Every disorder, however slight or localized, must give rise to reactions in every part of the organism. Sometimes the local reactions are manifest while the distal are too slight to produce recognizable effects. At other times the reverse is the case: the local reactions are so slight as to be overlooked, while the distal are manifest and predominate. Thus in one group of cases, although the primary site is in the higher nervous centres, yet the predominant effects show themselves as some bodily disorder. Many cases belong to this group. In the second and smaller group the primary site is a bodily lesion, but its chief effects take the form of mental disorder. A proof that these two groups exist is to be found in the fact that recovery takes place in each when—and not until—the primary seat is made right.

It is assumed here that one is dealing with a single physiological process acting upon an otherwise normal te, of m. There is, however, another aspect of the ication. Disease may arise in an organism which is rs. eady abnormal. Such dual pathology may be viewed si. om more than one angle. Thus it is well known that various fevers which make a normal person delirious may make mental patients, for the time being, less insane than before. The mental change in general paralysis during malarial infection is a striking example of this.

There is, however, still another point of view from which the interactions of the disordered mind and diseased body may be regarded—namely, that of the general physician. To what extent, and in what way, if at all, are the ordinary bodily diseases modified when they occur in persons already suffering from mental disorders? That is the question which this paper attempts to consider.

It is well known that in persons suffering from various mental disorders pain is often absent in the course of those bodily ailments which are usually very painful. This is not due to any self-control on the part of the patients, many of whom give vent to their troubles, real or imagined, with freedom and vigour. Actual bodily pain, due to some local disease, is, however, in my experience, rarely one of them. The result is that in many cases of mental disorder the standards of disease—that is, the particular combination and relative proportion of symptoms and signs—differ so widely from those seen in ordinary practice that the "clinical picture" is, at times, difficult or even impossible to recognize. This is familiar to those who work in a mental hospital, but to those of us who are accustomed to the standards of disease as met with in ordinary practice it causes surprise to see an intracranial tumour without headache, or a pneumonia without pain, cough, or loss of sleep. During recent years, as visiting physician to a large mental hospital, I have seen these anomalous "clinical pictures" repeatedly and in widely different conditions. They may be seen in diseases arising in any part of the body, but they have in common the absence, complete or partial, of important symptoms.

INTRACRANIAL LESIONS

In cases of intracranial tumour the absence of indicatory symptoms is a noticeable feature. In the post-mortem room of a general hospital it is unusual to find an intracranial tumour the existence of which has never been suspected during life. At a mental hospital this is by no means so rare. To suppose that this is due to any lack of observation or care on the part of those in charge of the patient would be unfair and unwarranted. The real explanation is that there has been a complete absence of characteristic symptoms and signs. It is difficult to make bricks without straw, and it is impossible for any but a charlatan to make a diagnosis without symptoms or signs. The following are typical cases.

Case 1.—A single woman, aged 35, epileptic and demented, had been an inmate of the institution for several years; she had always been very resistive and difficult. Pulmonary tuberculosis had been suspected, but none had been found. There had never been any change in her mental symptoms, and she had never at any time complained of headache. She began with symptoms of intestinal obstruction on May 31st, 1932, and died suddenly on June 2nd. At necropsy an obstruction by band was found, due to old caseous abdominal glands, and a tumour as big as a walnut in the left temporo-sphenoidal lobe.

Case 2.—A man, aged 63, was admitted on February 9th, 1932; there was no previous history. He was confused, and his gait was a little unsteady, but there was nothing definite about it. Hearing and sight were good and the pupils normal; the blood pressure was raised. The nineteen months that he was an inmate he was practically bed-ridden. No fresh symptoms developed, and there was no headache or vomiting throughout. At necropsy both lateral ventricles were found to be equally and greatly distended, due to an obstruction of the iter by a small angioma arising from its walls. In the absence of any history of this man's illness before admission it is not possible to form an opinion as to when and how the trouble began. It is well recognized, however, that these intraventricular obstructive growths usually give rise to paroxysms of severe headache. The fact that he had none for more than one and a half years before death is noteworthy.

Case 3.—A man, aged 59, was admitted on September 13th, 1933, with a history of confusion for six weeks. His gait was somewhat unsteady and he was shaky, but his speech was clear. There was no paralysis. The pupils were rather small, but equal. Reaction was sluggish. He had no headache and no vomiting throughout. He got up each day and sat about in the sick-room. On October 18th he collapsed suddenly in the afternoon, became more stuporose, and died on October 19th. At the post-mortem examination a tumour of the left frontal pole was found.

Case 4.—A man, aged 58, was admitted on June 26th, 1928, with the history that for three or four months he had had delusions of great wealth, and had had suspicions of his relatives. There was a strong family history of insanity on the father's side. His mental condition remained unchanged during the four years he was an inmate. In July, 1930, his gait became unsteady, and later he had some kind of seizure, in which the right side was affected, and a right hemiparesis resulted. There was no record of headache or vomiting while he was an inmate, and no visual disturbance or cranial nerve palsies. At necropsy, on June 12th, 1932, there was a large tumour at the base of the brain, compressing the right side of the pons. It was so firmly adherent to the base of the skull that its exact relation to the hypophysis could not be made out. In this case such signs as there were would have been of no value in locating the tumour had its existence been suspected.

INTRATHORACIC LESIONS

The clinical picture of intrathoracic lesions in cases of mental disorder is often different from that seen in normal patients. It is a general experience that the duration of pulmonary new growths, reckoned from the first appearance of pulmonary symptoms, is rather long; in other

words, they appear to give rise to symptoms from the first. In the following case no symptoms of illness of any kind occurred until four days before death, and there was no cough throughout.

The patient, a man, aged 68, with senile dementia, had been an inmate since 1925. He had old mitral disease well compensated. There was no change whatever in his mental condition or behaviour until March 14th, 1931, when he was noticed to be short of breath; there was no cough. He was removed to the sick-room and died on March 18th. The post-mortem examination revealed, in addition to the old mitral trouble, a new growth arising in the bronchus and involving the upper lobe of the right lung.

LOBAR PNEUMONIA

It is in lobar pneumonia that the absence of the familiar symptomatology makes such a change in the clinical picture. The signs in the chest, the course of the pyrexia, the P.-R. ratio, and the occasional herpes febrilis are all there, but the pain, the cough, the general distress, and, most of all, the restless, sleepless nights, may be entirely absent. Standing at the bedside of such a patient it is often difficult to believe that he is undergoing an attack of lobar pneumonia. In all of the following cases the patient recovered.

Case 1.—A man, aged 62, who had been an inmate for thirty years, suffering from chronic dementia, was noticed by the attendant to refuse his dinner on February 27th, 1932. He did not complain of anything, but his temperature was found to be raised, and he was removed to the sick-room. Consolidation was found at the right base. The temperature (102°-105°) during the seven days' illness, with a pseudo-crisis on the fifth and a crisis on the seventh day, were typical. Respirations ranged from 24 to 40, and the pulse from 84 to 112. Leucocytes, 12,000 per c.mm. He had no pain, dyspnoea, cough, sputum, or delirium, and he slept for seven hours every night.

Case 2.—A man, aged 72, with secondary dementia, had slight pain in the left side, slight cough, and a little blood-stained sputum at the onset, but slept five or six hours every night during the one week's fever; he had no delirium.

Case 3.—A man, aged 34, suffering from insanity with epilepsy, had slight headache at the onset, also a little cough, and some rusty sputum, but no dyspnoea. There was no pain in the chest at any time. The fever lasted twelve days, ending by lysis during the last five days. The patient's hours of sleep during the first ten days were: seven, seven, seven, seven, four, six, six, five, six, and six respectively.

Case 4.—A man, aged 59, was admitted in December, 1930, with secondary dementia, following alcoholic mania. In April, 1933, he had lobar pneumonia, right base. He had slight pain on the right side and a slight cough. The crisis occurred on the sixth day. The patient's hours of sleep on the first five nights were: seven, five, six, six, and five respectively. During the pyrexial period he was mentally brighter than usual.

Case 5.—A male, educable imbecile, aged 46, began vomiting on May 1st, 1932. There was no pain or cough, but he was found to be feverish, and he later developed lobar pneumonia. Throughout there was no cough, only slight pain on the right side, and some slight delirium in the early mornings. The fever lasted fourteen days, ending by lysis. His hours of sleep during the fever were: six, six, four, six, six, six, six, six, six, two, four, five, and six.

Case 6.—A male inmate, aged 29, with dementia praecox, usually very deluded, hallucinated, and impulsive, was found to have a temperature of 103° on May 22nd. He had a slight cough with bloody sputa on the fourth day, but no pain. He slept on an average five and a half hours each night of seven days' fever.

Case 7.—A man, aged 36, suffering from general paralysis of the insane (treated with malaria without permanent improvement) developed pneumonia on June 27th. The crisis occurred on July 5th. He had no distress at all, and no cough, sputa, or pain. He slept on an average six hours each night.

In pneumonia, as seen in daily practice, the combination of fever, pain, cough, and loss of sleep usually makes even the most amiable persons fretful and distressed. Indeed, the presence of euphoria is usually of ill omen. The old clinical aphorism "Beware of a pneumonia that smiles at you" contains more than a grain of truth. In these mental cases, however, the absence of distress is not due to poisoning of the higher centres, but apparently to their failure to register and respond to disturbing stimuli from the periphery. The pathological changes in the lung and pleura are the same in character and extent, but they call forth no obvious reaction on the part of the nervous system. The almost complete absence of cough is rather difficult to understand. In ordinary cases it is so frequent, violent, and often painful, that one looks upon it as the imperative reply to an urgent stimulus from within the respiratory tract; in other words, that it belongs to the late F. J. Smith's category "cough useful." Its absence in these cases without detriment to the course of the disease suggests that it is mere waste of energy, and must, however reluctantly, be relegated to his other class "the cough ornamental." The absence of cough and pain no doubt contributes largely to the long, sound sleep, but other psychological factors are probably also concerned. At any rate this steady succession of restful nights must play an important part in preventing exhaustion, and suggests that a free use of effective sedatives may do more good than harm.

In recording these atypical cases of pneumonia it must be understood that from time to time more typical cases occur in persons of unsound mind. In these, cough, pain, and restless insomnia are present. Much depends on the nature of the mental disorder, and the amount of possible reaction of the higher centres. It must also be added that in a certain number of cases of pneumonia diagnosis during life is out of the question. Such cases are those in which the patient presents no symptoms, and is in such a condition of resistive excitement that it is impossible to investigate physical "signs."

Of the other two common thoracic conditions—namely, tuberculosis and cardiovascular disease—I have not, as yet, collected sufficient information to give details. Considering the large number of necropsies in which gross cardiovascular changes are found, the rarity of anginal pain among the inmates is surprising, while in the tuberculosis annexe the comparative absence of coughing is very noticeable.

ABDOMEN

Organic lesions in the abdomen may not give rise to any pain or digestive disturbance. Thus in cases of serious, and even fatal, organic disease of the stomach there may be no discomfort, no vomiting, no tenderness on pressure, no local signs, and, most surprising of all, no loss of appetite.

Case 1.—A male, aged 54, suffering from delusional insanity, was noticed to be getting pale in May, 1933. Secondary anaemia was found. There was no pain after food, no vomiting, and no gastric symptoms. There was nothing palpable in the abdomen. Carcinoma of the stomach was diagnosed from the secondary anaemia. The patient took his food exceedingly well up to his death on September 18th, 1933. The post-mortem examination revealed a cauliflower carcinoma of the stomach with secondary nodules in the liver, left sub-phrenic abscess, and left empyema.

Case 2.—This man, aged 62, had been an inmate since 1906; he was suffering from secondary dementia following chronic mania. The only gastric symptoms at any time were a slight vomiting of dark fluid on June 26th, 1932, also slight vomiting on July 10th. He took his food well up to the time of his death on July 13th. He denied having any pain throughout his illness, and there was no tenderness or resistance on palpation. At necropsy there was a large malignant mass surrounding and constricting the pyloric opening, with secondary nodules in the liver.

Sometimes there is more definite, though slight, indication of the seat of the trouble; even then the absence of other symptoms may cause hesitation in diagnosis. In each of the following two cases a single slight haematemesis, occurring a week or two before death, was the only diagnostic clue to the seat of the lesion.

Case 1—A man, aged 61, had been an inmate since 1914, suffering from chronic alcoholic dementia. He had been in bed for the last twelve months. Two weeks before he died there was a slight haematemesis, but he never vomited before or after this. There was no pain after food, and no abdominal tenderness to be felt in the abdomen. He died on May 4th, 1933, and a post-mortem examination showed the size of an ulcer, 1.5 in. long on the lesser curvature of the stomach, with a secondary growth in the liver.

Case 2—A man, aged 67, suffering from general paresis of the insane, extremely aggressive, and demented, in whom malaria treatment had been necessary, was put to bed on March 6th, 1931, on account of weakness. There were no symptoms of any kind until a slight haematemesis occurred two months later, on May 2nd. There was no pain, no tenderness on pressure, and no abdominal tenderness. The patient's spirits were up to his death on June 1st, 1931. The post-mortem examination revealed an ulcerated growth on the lesser curvature of the stomach 3 inches in diameter. The stomach was full of blood; there were also collections and epiploic nodules, with ulcers in the spleen.

Ulcer of the Stomach

In cases of ulcer of the stomach or duodenum the absence of pain is very misleading.

Case 1—A man, aged 52, was admitted in May, 1928, suffering from melancholia with auditory hallucinations. He was excited, and stated that he was being tortured with pains all over. The mental condition persisted without any change to the end. On September 3rd, 1931, he was moved to the asylum for the last time, and he died on September 14th. He was excited and restless, and kept shouting out about being tortured by pains all over, but there was no particular localization of these to the abdomen, and he had been complaining in exactly the same way for three years. He died suddenly on September 14th. At necropsy there was a dilated aortic valve and a very large heart. The stomach was much congested. There was one rounded ulcer in the stomach and two in the duodenum, one of which had perforated. There was brown fluid in the inflamed peritoneum.

Case 2—A female, aged 73, who was suffering from senile dementia and chronic alcoholism; she had always been childish, chattering, and restless. No change was noticed in her appetite or general condition until the day before she died, when she seemed out of sorts and was put to bed. She was extremely restless to examination of any kind. She collapsed on the bed after a simple enema, and died rather suddenly. At necropsy a perforated duodenal ulcer was found. There was no history of abdominal pain, loss of appetite, or vomiting.

As in the case of carcinoma a haematemesis may prove a valuable clue, but even then the absence of the usual accompanying symptoms makes diagnosis difficult.

Case 3—A man, aged 52, with recurrent melancholia, had no symptoms until December 26th, 1932, when he had a slight haematemesis and complained of a little abdominal pain. He was put to bed. The next day he vomited half a pint of blood, and on the 28th about 8 ounces. He died on January 1st, 1933. The post-mortem examination showed an ulcer the size of a suppurative near the pylorus. In this case a correct diagnosis was made, and suitable medical treatment carried out. The point is, however, that except for the single occasion mentioned on December 26th, he had no pain throughout.

Case 4—The patient, a man aged 58, had been an inmate for ten years, and had delusional insanity with auditory

hallucinations. The first sign of illness was on October 21st, 1931, when he vomited and collapsed. In his case a swelling was felt in the left hypochondrium. There is a note that on October 22nd his diet was increased, and that there was no vomiting. On November 1st he vomited a little yellow fluid. He died suddenly the following day. At necropsy there was an ulcer on the anterior wall of the stomach the size of a lemon, which had perforated. The patient had no pain throughout his illness, and had taken his food as usual up to a week before his death.

Unfortunately, in cases of gastric ulcer in which symptoms are so few, little or no diagnostic help can be obtained from the various aids to diagnosis available in ordinary practice. Many of these require the co-operation of the patient to an extent rarely possible in mental cases. The passing of an ordinary stomach tube is too great a risk to be undertaken, except when necessary for feeding purposes, while a fractional test meal is in most cases out of the question. Similar difficulties attend the giving of an opaque meal for radiological purposes. Examination of the faeces for occult blood presents no such difficulties, but in the very cases in which it would be of value—namely, those of suspected ulcer—the only symptom which, as a rule, arouses suspicion is a haematemesis, and under such circumstances the finding of blood in the faeces does not add to our knowledge. Should an abdominal growth obstruct the bile passages jaundice may occur, and is a valuable diagnostic sign. If it does not, in the absence of all pain and tenderness in the liver region, there may be no suspicion of the presence of a growth.

Case 5—A female, aged 76, an inmate since 1908 with melancholia, had been bedridden since 1927 with pulmonary tuberculosis. For the last year or three months of life she became gradually more restless, and took less food, but she had no symptoms at any time pointing to liver trouble. There was no jaundice and no pain throughout. At necropsy, on April 2nd, 1931, there was a primary carcinoma of the liver.

The symptom most commonly absent is thus seen to be pain. No doubt the reason for this varies in different forms of mental disorder. In some it may be that there is actual deficiency of available receptive material, somewhat comparable to the temporary effect of narcotic drugs. In others it may be that the receptive material is there, but that it is fully occupied in dealing with other and stronger stimuli. There is also the possibility of a painful stimulus being converted into something not painful, as in Pavlov's experimental dog, in which a painful electric stimulus, when made part of a conditioned reflex for feeding, causes no signs of pain, but merely those of anticipatory pleasure. Whatever the explanation, the question arises: How far does the individual mental patient gain or lose by this absence of symptoms?

To be spared pain in a hopeless, fatal disease is a great boon. When, however, the condition is one in which recovery, either with or without operation, is possible, the absence of pain is a serious loss, because it makes early diagnosis and appropriate treatment impossible. On the other hand, in such a condition as lobar pneumonia the mental patient seems to gain in every way. Whether the mortality of pneumonia is less in mental hospitals than elsewhere I have no data on which to form an opinion. If it is less the gain is considerable; even if it is greater, at least those affected have a smoother crossing.

The frequent absence in these patients of reflex actions, such as coughing and vomiting, when one would expect them to be present, suggest that they are not such simple affairs as they would seem, and that even when their occurrence might reasonably be attributed solely to the lower reflex mechanism concerned with the particular area affected, centres at a higher physiological level play a larger part in the act than is usually supposed.

In conclusion, I would call attention to the work of the nurses and attendants at our large mental institutions. I have been impressed by the quickness and the sureness with which they detect the onset of bodily illness in the inmates under their charge. Usually it is by some very slight change in behaviour or appearance, either not eating their dinner or being less irritable, or perhaps some change in their colour. This is noted and reported at once. Their duties are often exceedingly trying, and if anything goes wrong public sympathy is not usually on their side. It is therefore a pleasure to take this opportunity of stating that those with whom I have come in contact have shown a care and interest in the patients under their charge which is in every way worthy of praise. I am much indebted to members of the medical staff of the South Yorkshire Mental Hospital for help in preparing this paper, especially to Drs. Gillespie and Mathieson for clinical records, and to Dr. Thorpe for pathological notes. For permission to make use of the material and for every assistance in so doing, my thanks are due to Dr. W. J. Vincent, medical superintendent of that institution at the time.

SOME OBSERVATIONS ON ACHLORHYDRIA AND ANAEMIA *

BY

STANLEY J. HARTFALL, B.Sc., M.D., M.R.C.P.

HONORARY PHYSICIAN, LEEDS PUBLIC DISPENSARY AND HOSPITAL;
LEVERHULME RESEARCH SCHOLAR, ROYAL COLLEGE OF
PHYSICIANS OF LONDON

We define achlorhydria as the condition in which there is an absence of free hydrochloric acid in the gastric juice. Actually we do not often test directly for this acid. Knowing that a certain degree of acidity (pH 3) can, in practice, only be due to hydrochloric acid, the direct chemical test becomes unnecessary. If no portion of the gastric juice is acid to a certain indicator (that is, red to Töpfer's reagent) no free acid can be titrated: this is achlorhydria in the usually accepted sense, and in this sense is employed here.

TESTING FOR ACHLORHYDRIA

We have at once to recognize that failure to secrete acid on carrying out a test upon the stomach may vary to some extent in the same individual and also with the stimulus to secretion which is employed. By applying a powerful stimulus to gastric secretion we may call forth acid which a milder stimulus may fail to provoke.

An ordinary meal is presumably the most natural physiological stimulus to the secretion of gastric juice, and the earlier tests of gastric secretion made use of 2 oz. of dry toast and 8 oz. of unflavoured tea (Ewald), or 1/2 oz. of boiled rolled oats reduced to a pint (Ewald-Boas). This material, after remaining in the stomach for three-quarters of an hour, was withdrawn and tested. This form of test is still in vogue on the Continent, and many of the older statistics relating to achlorhydria, both here and in America, are based upon it. The principal objection to this test is that all the stomach contents are withdrawn after they have remained in the stomach for, say, three-quarters of an hour, and we learn nothing about secretion after this. In some persons there may be a considerable delay in the production of acid, and it is easily possible that a case which is achlorhydric according to the Ewald test, may not actually be so. The incidence of achlorhydria, using this test, therefore tends to be high.

The fractional test meal, popularized by Rehfuss in America and Bennett and Ryle in this country, and used in this hospital, consists in withdrawing samples of the gruel meal, administered after the fasting juice has been withdrawn, at quarter-hour intervals for three hours. Each sample may be analysed, and a dynamic picture of the fluctuations of gastric

secretion during digestion is obtained. Delayed acid secretion will usually be revealed, and statistics demonstrating the incidence of achlorhydria based on this test show that it is rather less common than the Ewald test would suggest.

Recently the introduction of a powerful stimulant to gastric secretion which can be administered subcutaneously has given considerable impetus to further studies. This drug—histamine—administered in suitable dosage, according to body weight of the individual, causes, within a very few minutes, a copious flow of gastric juice unaccompanied by any other disturbance. The gastric juice so obtained is pure and uncontaminated by food, and is eminently suitable for analysis. Histamine is probably the most powerful stimulant to acid secretion we possess, and when a case fails to secrete acid following the appropriate dose of histamine, it is truly achlorhydric. A proportion of cases achlorhydric in the fractional test meal do produce acid on histamine stimulation.

ITS DISTRIBUTION

The incidence of achlorhydria as shown by these various tests by different workers, for all age periods, is probably about 14 per cent. My own series, collected from patients under Dr. A. F. Hurst at the New Lodge Clinic, is comfortably average (13.7 per cent.).⁶ I think the inference we can draw is that about 14 per cent. of the average population of all ages is achlorhydric. Nearly all observers have found that achlorhydria is commoner in females than in males. This was so in my series for all age periods, except between 20 and 40 years. This higher incidence among healthy females is disclosed also when histamine is used. The influence of age has become of considerable importance because of its bearing upon the hereditary, constitutional, and acquired factors which predispose or actually induce achlorhydria and related disturbances in gastric secretion. All types of tests of gastric secretion (including the most recent ones with histamine) show that the incidence of achlorhydria increases with age. This was especially noteworthy in my own series among females beyond the age of 40. Information about achlorhydria in infants is a little uncertain, but beyond the age of infancy we know that the incidence slowly and surely increases. When large series of investigations are put together this increase occurs with a regularity and smoothness which suggests that a true biological fact is revealed.

ITS PATHOLOGY AND SIGNIFICANCE

We have next to consider how, or by what mechanism, achlorhydria develops, and what is its significance. Complete proof does not exist that changes in the mucous membrane of the stomach always and necessarily accompany achlorhydria. The necessary correlations between impaired gastric secretions and the histology of the cells of the mucous membrane of the stomach at all ages have not yet been made. The association of achlorhydria with so many diseases, however, strongly suggests that in a large majority of cases it must have a very definite pathological significance. At the same time we must recognize that its presence may be compatible with apparent normal health, although there are many who believe that achlorhydria always has a serious significance, if not at the moment, then certainly in the future. We cannot ignore the nervous factor. We know that nervous influences, emotional upsets, and psychological factors may play a part in inhibiting gastric secretion. The very emotional upset which may accompany the passing of the stomach tube in a nervous subject may be sufficient to inhibit the acid secretion for a time. In such a patient, employing the older methods, achlorhydria might result according to the first test, and free acid would be obtained

* A lecture delivered to the Leeds and West Riding Medical-Chirurgical Society, November, 1933.

when the test was repeated. Acid secretion can also be suppressed by suggestion, as, for example, fear suggested under hypnosis. If such are the effects of transient emotional stimuli, it is possible that more permanent changes may be induced through the visceral nervous system by prolonged emotional stimuli, such as the fear element which is associated with psychoneurotic states. For many years it has been maintained that constitutional factors play an important part in the aetiology of achlorhydria. The evidence afforded by test meals carried out on newborn or very young babies is at present equivocal. On the whole, the incidence of achlorhydria is sufficiently high to suggest that some (genotypical) inherited factor is at work. Further support for this view, however, is found by the tendency of achlorhydria to occur in many members and several generations of one family. Thus Conner found 25.9 per cent. achlorhydria among 154 blood relatives of patients suffering from pernicious anaemia. This constitutional factor becomes of importance when we consider those instances of familial pernicious anaemia, simple achlorhydric anaemia, and families which show both these diseases and symptomless achlorhydria (Gram,⁵ Witts,¹⁶ Heath,¹¹ Witts and Hartfall¹⁷).

ACHLORHYDRIA AND CHRONIC GASTRITIS

Having considered achlorhydria from the point of view of heredity, the next point is to consider the definite underlying pathology of the gastric mucosa which most commonly accompanies achlorhydria—namely, chronic gastritis. The view that chronic gastritis accounts for the development and persistence of achlorhydria was first put forward by Hayem and Faber,⁴ and has many supporters. It is well established that all stages of chronic gastritis, even to complete atrophy of the gastric glands, may be found in the gastritis of pernicious anaemia, and to a less extent in simple achlorhydric anaemia, Graves's disease, etc. It is possible that alterations in the functional secretory capacity of the stomach may precede demonstrable chronic gastritis. Inspection of the gastric mucous membrane in cases of achlorhydria during life by means of the gastroscope, however, frequently reveals a changed appearance of the mucous membrane which is interpreted as chronic gastritis. There is one other aspect of the aetiology of achlorhydria which must be mentioned. Vanzant and Alvarez,¹² and also Pollard,¹ have shown that the average acidity for healthy individuals is higher in males than in females. In both sexes, as age advances, this average or mean acidity is progressively lowered. Finally, achlorhydria is reached, and among females it is reached, on an average, earlier. The higher incidence among women is accounted for by the above findings carried to their logical conclusion. If gastritis cannot account for these phenomena the alternative is to regard them as "involutional changes," the secreting mechanism becoming "played out" upon slight provocation, or spontaneously (Bloomfield and Pollard¹).

My own belief, which I find most useful in understanding this difficult problem, is as follows. I believe that there exists a hereditary predisposition to the cessation of normal gastric secretion, the basis of which is a gastric mucous membrane of functionally subnormal type. This subnormal mucosa may easily be disturbed by various factors. Many of these injurious agencies are exactly those which cause gastritis, and, in this particular inherited hyposecretory type, achlorhydria quickly results. The multiplication of these injurious factors as age advances accounts for the increasing incidence with age. The higher incidence in females can only be accounted for by the strain which the reproductive functions—menstruation, pregnancy, and lactation—throw on the economy of the female organism.

ITS CLINICAL APPLICATIONS.

What, then, is the clinical importance of this condition of achlorhydria? The best evidence of its importance is obtained by a consideration of those diseases with which it is associated and especially those which it precedes, where it is regarded as an essential predisposing condition to the disease in question.

1. It almost invariably precedes and accompanies true Addisonian pernicious anaemia and subacute combined degeneration, and it persists after the cure of the blood and nervous condition.

2. It precedes, accompanies, and persists after the cure of the simple achlorhydric anaemia—the most important member of the chronic microcytic group of anaemias.

3. It precedes and accompanies the commonest type of carcinoma of the stomach—that is, carcinoma *ex gastritis*.

4. It is present in an ill-defined group of conditions of ill-health where chronic gastritis often exists; it accompanies frequently the asthenic neurotic diathesis, conditions of gastro-intestinal irregularity and upset, debility, and, often, soreness of the mouth and tongue. It is also present in a significant proportion of cases of rheumatoid arthritis, asthma, and allergic diseases, Graves's disease, diabetes, etc., where its exact significance is disputed.

5. It may result from a variety of gastric operations (to be considered later), and in a proportion of them seems to account for certain post-operative conditions of chronic ill-health.

6. It may be encountered in normal health, when its prognostic significance is disputed.

It is important to realize that the suggestion is not made that mere lack of hydrochloric acid secreted in the stomach is directly responsible for every symptom associated with these various disorders; sometimes this may be the case, but more often the achlorhydria is simply an indication that something is wrong with the secretory apparatus, and that combined with this defect in acid secretion are other defects which are more directly concerned with the particular pattern of ill-health which may be present. So far as the blood is concerned with these gastric secretory changes, the loss of acid is not always the most important thing.

CLASSIFICATION OF ANAEMIAS

A simple classification of anaemia based on modern work is given in Table I. It shows us that the two forms of anaemia in which achlorhydria is commonly found are closely related from the aetiological standpoint. Both are examples of failure of proper maturation or development of red cells, due to the lack of some agent or principle necessary for their complete development. This incomplete development has been called by Witts "anhaemopoiesis," and the whole group of anaemias, the "anhaemopoietic anaemias."¹³

TABLE I.—Classification of Anaemia

Blood Loss :	Blood Destruction :
Acute.	Haemolytic anaemias
Chronic.	Acute (Lederer), poisons, of pregnancy, etc.
	Chronic acquired, acholuric jaundice, etc.

Inhibition of Blood Formation :

Anhaemopoiesis: Complete—aplastic anaemia.

Incomplete—arrested maturation of red blood cells due to deficiencies. (A) Megalocytic anaemia—for example, Addisonian pernicious anaemia (due to deficiency of anti-pernicious anaemia factor). (B) Microcytic anaemia—for example, simple achlorhydric anaemia (due to failure of absorption or utilization of iron).

Anhaemopoiesis

Group A.—Classical Addisonian pernicious anaemia is characterized by a tendency for the majority of the circulating cells to be larger in size, and often carrying more haemoglobin per cell. The bone marrow shows megaloblastic degeneration. The colour index is high. The anaemia is therefore megalocytic, and is also called hyperchromic, though the latter is a bad name. The anaemia develops when the anti-anaemic principle, as found in the liver, is deficient. This principle, in turn, depends upon the presence of an active ferment-like substance in the gastric juice, called haemopoietin,¹⁴ and its interaction with certain extrinsic substances associated with the proteins of the diet. The product must be satisfactorily absorbed through the gastro-intestinal mucous membrane, stored in the tissues (especially the liver), and utilized according to the demands on the bone marrow. It is possible that an anaemia of pernicious type may develop when any of the phases in the formation and absorption of the anti-anaemic principle fails. Thus, in Addisonian pernicious anaemia the intrinsic factor of Castle (haemopoietin) is absent; in tropical megalocytic anaemia the extrinsic factor is absent. In the megalocytic anaemia of sprue, fatty diarrhoea, multiple stenoses and strictures, and intestinal parasites, either the gastric digestion or the absorption of the factor fails. In gastric carcinoma and in Graves's disease the intrinsic factor occasionally disappears and a megalocytic anaemia develops, and similar changes may occasionally be encountered after severe gastric operations. To recapitulate: broadly speaking, in the Addisonian-pernicious-anaemia-subacute-combined-degeneration syndrome the most important and fundamental defect is a gastric one—the loss of the intrinsic factor of Castle (haemopoietin), which is a product of the normal gastric mucous membrane.

Group B.—The second, or microcytic, type of anaemia contrasts in many respects with pernicious anaemia; for the majority of the circulating red cells tend to be slightly smaller than normal, and their haemoglobin content per cell is reduced in much greater proportion. The colour index is low. The bone marrow shows normoblastic reaction. The anaemia is therefore microcytic and hypochromic. It does not respond to liver or stomach preparations, but, being due to a deficiency in iron, it responds to treatment with certain iron preparations, though they must be given in large doses. Achlorhydria is very common in this anaemia, which is largely confined to women. It includes simple achlorhydric anaemia and the Plummer-Vinson syndrome; the microcytic anaemias secondary to pregnancy, Graves's disease, etc.; the anaemia of cancer of the stomach; and that following gastric operations.

Comparison of Two Groups

The next problem is to consider how far the defects in gastric secretion are comparable, and whether they have an equal significance in this second microcytic form of anaemia, as they appear to have in pernicious anaemia. It was with this aspect of the problem that Dr. Witts and I were chiefly concerned.^{15,16} It soon became apparent that for practical purposes achlorhydria (with gruel test meal and histamine) occurred in 100 per cent. of cases of true Addisonian pernicious anaemia; in chronic megalocytic anaemia, although more than 80 per cent. were achlorhydric in the gruel fractional test meal, a proportion of cases could be made to secrete small quantities of acid with histamine, and thus were really hypochlorhydric. The cases investigated were therefore subdivided into true simple achlorhydric anaemia, and a small group of chronic microcytic anaemia with hypochlorhydria.

Our principal findings in the gastric secretion of these groups of cases are shown in a summarized form in Table II. Briefly, it will be seen that there is a striking

TABLE II.—Histamine Secretion in Anaemia with Achlorhydria

	Normal		Addisonian Pernicious Anaemia (25 Cases)		Chronic Microcytic Anaemia

Intrinsic Castle factor	Present		Absent		Traces?		Reduced	

gradation in the severity of the gastric defect in all three groups of cases as shown by examination of the histamine gastric juice. This is seen to affect all the elements of gastric juice investigated—the ten-minute volume secretion, the hydrochloric acid, total chloride, pepsin, insoluble mucus, and soluble mucoprotein. It was noteworthy that sometimes the gastric secretion of simple achlorhydric anaemia might be indistinguishable from pernicious anaemia, but whereas the defects in pernicious anaemia were constantly found to be most severe, occasionally in simple achlorhydric anaemia the changes would be less severe. In the hypochlorhydric group the changes were found to be least severe, although deviating widely from the normal.

If, then, the gastric secretions in these anaemias in so many respects closely resemble one another, in what respects do they differ? Experiments were carried out to demonstrate the presence or absence of the intrinsic factor in the gastric juice of patients suffering from simple achlorhydric anaemia. Witts and I were able first to confirm the absence of the intrinsic factor in the gastric juice of pernicious anaemia as first shown by Castle, but in the case of simple achlorhydric anaemia our results were not entirely in conformity with the original Castle hypothesis. Briefly, we found that the factor was present, but much reduced—sometimes to the point of absence. When we considered the details of the analysis of the gastric juice of those cases of simple achlorhydric anaemia which apparently possessed practically no intrinsic factor, we were impressed by the fact that they were always those cases in which gastric secretion was most impoverished, and they usually secreted no pepsin. When we repeated the experiments, using selected cases which secreted no pepsin, the result was negative. We therefore suggested that the reduction of the intrinsic Castle factor is parallel with that of other gastric ferments, but it was evident that, in general, there must be sufficient intrinsic factor secreted somewhere in the economy of these patients to hold off the development of megaloblastic degeneration of the marrow, and to prevent pernicious anaemia. If this were not so, the transformation of simple achlorhydric anaemia into pernicious anaemia would be commonly observed. Although occasionally recorded, the transformation of one type of anaemia into another in its clinical and haematological entirety is not common.

What relation, then, has the defect in gastric secretion to the anaemia of this chronic microcytic type, and why is it almost exclusively confined to women? The achlorhydria can best be considered, as Davidson⁷ suggests, as one of several grave disabilities which predispose to its development. The other disabilities are conditions which strain, as it were, the internal mechanism of blood formation by an excessive demand. They are conditions of chronic blood loss, and especially of excessive menstruation, repeated pregnancies and parturition, and the drain of lactation. If such disabilities operate together, and especially if the diet is only of minimum iron content (but adequate in the absence of these disabilities), then this microcytic hypochromic anaemia results.

To summarize this view. In a mixed population on an iron minimal diet the high incidence of achlorhydria and the drain of the reproductive functions accounts for the incidence of this anaemia in women. When we can reproduce such factors in men a similar type of anaemia develops.

As to the exact mechanism by which the achlorhydria interferes with the iron absorption, it has been shown by Mettler and Minot that iron is not easily absorbed from the upper gut in the absence of hydrochloric acid and pepsin. The question of the alteration of the pH of the duodenum by the iron salts employed may also be of importance (Langmead). I personally believe that other dietetic factors play a part, but this is not the place to discuss my results.

OTHER EXAMPLES OF ANHAEMOPOIESIS

The anaemias of carcinoma of the stomach and Graves's disease, and that following certain gastric operations, also provide examples of anaemia of anhaemopoietic type, and they may be megalocytic or microcytic.

Anaemia of Carcinoma Ventriculi

Cases of carcinoma of the stomach which present as examples of severe anaemia, often like pernicious anaemia, are familiar to all of us. These patients are not anaemic because of a large haemorrhage, for most surgeons will agree that such a catastrophe is a rare incident in cancer of the stomach. At the same time it is quite certain that continuous oozing of blood from the ulcerated growth surface commences at an early stage in its development, and is responsible for that valuable diagnostic finding—a positive occult blood test. This type of patient will not admit to a long dyspeptic history, and often the dyspepsia is minimal, the impairment of appetite being all that is complained of. The test meal examination of the stomach shows achlorhydria. Here, then, we have exactly those factors called "disabilities" which in women predispose to the development of chronic microcytic anaemia. The commonest type of anaemia associated with cancer of the stomach is of this type, and really is a simple achlorhydric anaemia. This is the type of cancer which develops on the basis of an unhealthy gastric mucous membrane—a gastritis, in fact—the gastritis and achlorhydria preceding the development of the carcinoma. If the anaemia in cancer is of gastrogenous origin it might be expected that anaemia of pernicious type would occasionally be associated with cancer of the stomach, and such cases have been recorded (Wilkinson has recorded two, and collected twenty-five others). In these individuals, irrespective of the presence of the growth, the intrinsic factor is lost, and the megalocytic pernicious anaemia develops. The importance of this is that both anaemias may for a time respond to their respective remedies, and the growth may be unsuspected. The pernicious type responds to liver for a time, and the microcytic type to large doses of iron. I have reported several such cases.¹⁰

Anaemia associated with Graves's Disease

Anaemia associated with Graves's disease is not rare. It is usually of the secondary microcytic type. Occasionally Graves's disease and pernicious anaemia are associated. I believe the achlorhydria and the associated defects in gastric secretion, which are common in cases of prolonged thyrotoxicosis, play an important part in the production of the anaemia. Among ten cases of pernicious anaemia associated with Graves's disease, and mentioned in a paper with Dr. Meulengracht of Copenhagen,¹² all were achlorhydric, and all were females.

Anaemia associated with Stomach Operations

Lord Moynihan's case of complete gastrectomy, ultimately resulting in death from severe anaemia, thought to be pernicious, was one of the first recorded examples of anaemia due to operative interference with the stomach. Since that time a number of similar cases have been reported, and it is now known that frequently such patients do develop anaemia, and that in complete gastrectomy its onset may not be long delayed. In partial gastrectomy, in proportion to the extent of the removal of the acid-secreting area of the stomach, so will achlorhydria result. The development of anaemia may be long delayed. After gastro-enterostomy achlorhydria does not as a rule follow, though the abnormal conditions present in the stomach frequently result in gastritis, which may ultimately cause the cessation of acid secretion. The free regurgitation of duodenal contents, and rapid neutralization of small quantities of acid, makes the certain demonstration of achlorhydria difficult in many of these cases. I have twice found achlorhydria after a faulty gastro-enterostomy has been undone, although free acid was present in normal quantities before the original operation. The type of anaemia which occurs after these operations again belongs to the anhaemopoietic group, and is frequently of the chronic microcytic type. Occasionally a case of partial gastrectomy pernicious anaemia is encountered.

Anaemia after gastric operations seems to occur most frequently among those unfortunate individuals who are suffering from what may be called the ill results of gastro-enterostomy. If such a group of individuals be investigated, in addition to their innumerable abdominal discomforts, a proportion of them will be found to be definitely anaemic.

In a small group of twenty patients (ten male and ten female) investigated by me, who had become chronic abdominal invalids following operation upon the stomach, seven females had anaemia of secondary type, and five of these had developed gastro-intestinal hurry, as shown by x-ray examination. It is possible that the disturbed physiology of the gastro-intestinal tract had so interfered with digestion and absorption of iron that adequate quantities could not be absorbed and utilized for the manufacture of haemoglobin. In only one case had traces of occult blood, due to gastro-jejunal ulceration, been found.

Among 112 traced cases of gastrectomy for ulcer there were twenty-one deaths and, thirty-six patients who complained of some degree of unfitness, and whose blood was examined. Among the thirty-six, twenty-two had some microcytic anaemia, and one was a case, since dead, of ? pernicious anaemia.

Of thirty traced cases of gastrectomy for cancer, twenty-one patients were dead, and of the nine alive and seen, six made some complaint of unfitness, and their blood was examined. Two of them, both females, had chronic microcytic anaemia.

Putting all these cases together as examples of individuals unfit after gastric operations, there were sixty-two unfit persons among 168 cases of gastric operations. Of this number (sixty-two), thirty-one were anaemic—that is, 50 per cent. of the unfit patients were anaemic. When the sex of the affected patients was considered

80 per cent. were found to be females. Here again there seems to be evidence that when the female organism is subject to the added disability of disturbed gastric physiology consequent upon unsatisfactory gastric operations, anaemia of the anhaemopoietic type develops.

TREATMENT OF ACHLORHYDRIA AND RELATED ANAEMIAS

I cannot hope to deal with every aspect of treatment which concerns achlorhydria and the related anaemic states which have been mentioned. With regard to achlorhydria much depends upon the view we take of its aetiology and the part we believe it to play in producing the associated condition. While the associated disease is obvious and urgent we treat it—for example, the anaemia—and we are well content to cure it. But we may well question whether this is sufficient, for our patients are left with the achlorhydria and the pathological condition of the stomach which underlies the achlorhydria. How far does this predispose to further complications or even new diseases? What will be the incidence of carcinoma of the stomach among patients cured of pernicious anaemia, in ten or twenty years' time? How many of them will develop biliary infections if the achlorhydria is ignored? Hurst suggests that we must always consider the treatment of achlorhydria as well as the associated disease, and also we must try to prevent these diseases by early treatment of the achlorhydria. This implies the prevention of gastritis by the elimination of all preventable forms of gastric irritation, a complete overhaul for all sources of open or focal sepsis, especially in the mouth, pharynx, and accessory sinuses. The restoration of gastric acidity may often be brought about by the old treatment of gastric lavage. Thus among thirty-four cases of achlorhydria at New Lodge Clinic³ treated by daily gastric lavage (one ounce of hydrogen peroxide to the pint) acid returned in 82 per cent. of cases.

Hydrochloric Acid

In those cases where general slackness and debility with gastro-intestinal symptoms accompany the achlorhydria, astonishing results may sometimes be brought about by the substitution of hydrochloric acid. The remarkable fact is that the dose of hydrochloric acid given is often quite insufficient materially to affect the reaction of the achlorhydric stomach, yet the abrupt cessation of gastro-genous diarrhoea, perhaps of years' duration, seems little short of miraculous. Larger doses, well diluted, and flavoured suitably with the addition of pepsin, are often useful where dyspepsia and gastro-intestinal upsets are present. In the treatment of the anaemias associated with achlorhydria, as in the case of pernicious anaemia, the problem is to select from the innumerable preparations offered to us the most economical remedies consistent with full activity and convenience in administration.

Liver

Emergency treatment practically only exists in the case of pernicious anaemia, and the introduction of safe intravenous liver preparations has, for practical purposes, rendered transfusion unnecessary. Transfusion is now only needed when severe infection inhibits the effect of the active preparation. The dose of these intravenous liver products in an emergency is 5 c.cm., and this calls forth a reticulocyte response within twenty-four hours as a rule. From 2 to 4 c.cm. may be given the next day, followed by intramuscular preparations, 2 c.cm., according to the magnitude of the blood response and the clinical progress of the case. Within a week or ten days these patients can be given preparations by mouth, and finally, by trial, the maintenance dose determined. For less acute cases treatment can be started with intramuscular preparations

which cost only half the amount of the intravenous ones, and then preparations by mouth. It is most important that patients should be made to understand the necessity of continuing with the adequate amount of active preparation. Nothing can be more deplorable than the case which is allowed to drift on with haemoglobin below 80 per cent. and red corpuscles below 4,000,000. The risk of development of nervous symptoms, and the chance of curing them if present, depend upon the maintenance of the blood at the level of health. For maintenance treatment it is necessary for the medical man to be able to recommend active preparations in which he has absolute confidence, and at the same time to save his patient unnecessary expense—for many of the most expensive products are in no way superior to certain much cheaper and reliable preparations on the market.

Stomach Preparations

Providing the patient is on ordinary mixed diet, there is no special virtue in whole liver that is not possessed by active liver extracts and stomach preparations. Few patients will continue to take whole liver for two meals a day for the rest of their lives. The dry extract is very expensive and unpalatable; the liquid extract is not pleasant, but is less expensive. On the whole, I believe that stomach preparations are best adopted as a routine, on grounds of economy, convenience in administration, and effectiveness; there are very few cases that cannot be kept with haemoglobin between 95 and 105 per cent. upon one ounce of stomach preparation a day. They are also helpful in controlling associated dyspepsia and improving the nervous symptoms of subacute combined degeneration. The price of stomach preparations is very variable, and much money can be needlessly expended. The more elegant preparations are expensive because of the cost of removing fatty matter, which gives the cheaper preparations their unpleasant odour. Very few patients in my experience are unable, after two or three days, to tolerate even the cheap fat-containing preparations, the cost of which is even less than that of 1/2 lb. of whole liver per day. Purely from the cost point of view, at the present time, treatment by intramuscular preparations given twice weekly would be only half that of treatment by mouth preparations. Large doses of the intramuscular preparations have been injected to form depots without ill result. These depots are slowly used up, and need replenishing at longer intervals of time.

Infection and septic foci retard the effect of treatment. I have seen a case fail to respond while an infected antrum was untreated. In females I would stress the frequency of *B. coli* pyelitis as a cause of unsatisfactory progress. This was the commonest infective complication interfering with treatment among 400 cases reviewed at Copenhagen in Meulengracht's Clinic. Pregnancy and lactation are indications to increase the maintenance dose of the active preparation.

Iron

The treatment of chronic microcytic anaemia, depending as it does chiefly on large doses of iron, is fortunately cheaper than that of pernicious anaemia. Here, too, the necessity for very prolonged treatment must be emphasized, otherwise these women relapse into a miserable state of chronic ill-health. It is now common experience that ferrous salts of iron are most rapidly and uniformly successful. The cheapness of these salts makes the large dose of no account. Successful treatment may usually be achieved by the following:

Bland's pill, fresh (ferrous carbonate), 60 grains daily.
Feronyl (ferrous chloride), 6 to 9 tablets daily.

Ferr et ammon. cit.	{ mixed ferrous and	45 grains daily.
Ferr et quin. cit.	{ ferric in colloidal state	

Tab ferri carb. sac. (ferrous carbonate), 45 grains daily.

These doses of iron preparations are the *minimal* effective doses, and in resistant cases it may be necessary to double the dose here indicated. Colloidal and organic iron compounds are much less effective.

Vitamins

I usually augment this massive treatment with certain vitamin preparations such as bemax or marmite 1/2 ounce daily, or yeast compressed into 5-grain tablets. Some of these patients are almost certainly suffering from vitamin B deficiency, and I have had several cases which have improved upon these vitamin B containing preparations without any iron whatever. Infection, sepsis, pregnancy, and lactation all inhibit the response of these patients to iron, and in selected cases, where menorrhagia is present, artificial induction of the menopause may be necessary before improvement will take place.

THE HAEMATOPOIETIC RESPONSE TO INTRAMUSCULAR INJECTIONS OF CONCENTRATED HUMAN GASTRIC JUICE

BY

PAUL J. FOUTS, M.D., O. M. HELMER, PH.D.,

AND

L. G. ZERFAS, M.D.

(From the Lilly Laboratory for Clinical Research, Indianapolis City Hospital, and the Department of Medicine, Indiana University School of Medicine)

Morris and his associates¹ recently reported that although small amounts of normal human gastric juice were ineffective when injected intramuscularly, large amounts of normal human gastric juice or hog gastric contents after concentration *in vacuo* produced maximal reticulocyte responses when injected into patients with pernicious anaemia. They described the substance in the concentrated gastric juice as being thermolabile, dialysable, and exhaustible, and therefore concluded that it was probably a hormone. Conner² reported similar results in one case of pernicious anaemia, following the injection of normal human gastric juice after concentration by vacuum distillation. Wilkinson³ was unable to confirm the findings of Morris and his associates when he injected human gastric juice that had been brought to pH 7.5 previous to its concentration *in vacuo*.

The observations here recorded were carried out in order to determine whether it was possible to separate the "active principle" in the gastric juice from the known enzymes (pepsin and rennin) by the process of ultrafiltration. This process not only offered a means of determining the relative size of the various constituents of the gastric juice, but also a possible method of concentrating the gastric juice at ice-box temperatures.

METHODS

The patients, clinically and haematologically typical of pernicious anaemia, received the concentrated gastric juice intramuscularly after preliminary control periods (average seven days). Red blood counts, haemoglobin determinations (Newcomer), and reticulocyte counts were made daily during the control and test periods. The human gastric juice used was obtained from young healthy adults following the injection of 0.5 mg. of histamine subcutaneously. It was filtered immediately after collection through a No. 1117½ Faltenfilter (Carl Schleicher and Schüll). The enzymatic content of the gastric juice to be concentrated was determined by methods detailed previously.⁴

The Bechold type of ultrafilters described by Bronfenbrenner⁵ was used in the experiments. The gastric juice (285 to 630 c.cm.) was concentrated by these ultrafilters, and twice diluted with distilled water or 0.3 per cent. hydrochloric acid, and reconstituted before being brought to the final volume of 13 to 15 c.cm. This procedure was carried on in the ice-box. Since only negligible amounts of pepsin and rennin passed through these filters, each new filter could be tested for possible defects in the construction by determining the amounts of these known enzymes in the ultrafiltrate.

In a preliminary study it was found that the "active principle" in liver extract No. 343 passed through the ultrafilters. One patient (Case 9) had a reticulocyte peak of 25.6 per cent. (absolute reticulocyte count 620,000 per c.mm.) following the intravenous injection of the amount of liver extract derived from 100 grams of whole liver, after the extract had been passed through the ultrafilter.

In the experiments in which concentration by vacuum distillation was employed the procedure was as follows. The distilling flask (fitted with the usual capillary tube to prevent bumping) was immersed in a constant temperature bath maintained at 40° C. The vacuum was produced by a water pump. The gastric juice (500 to 600 c.cm.) was concentrated to 10 to 15 c.cm. in a period of three to five hours. The gastric juice concentrated by either or both of the above methods was sterilized by passing through an N Berkefeld filter, or by the addition of a few drops of tricresol, and was adjusted to a pH 7 (at ice-box temperature) by the addition of strong NaOH before being injected into the patients.

RESULTS

In the first group of observations (Group 1) the gastric juice used had been filtered through paper and then stored in the ice-box for approximately two months before being subjected to ultrafiltration. The effect of the two injections of the concentrated juice (that held back by the ultrafilters) is shown in Chart I, Case 1. The clinical response in the patient was only slight, and the increases in the red blood count were not sustained. A further rise in reticulocytes and a satisfactory rise in red blood cells followed the administration of extralin* by the mouth. The ultrafiltrate (the portion passing through the ultrafilters) of this juice was concentrated by vacuum distillation and injected into Case 2a. No response of the blood occurred during the following twelve days.

These reticulocyte responses were not maximal; therefore it was decided that fresh gastric juice should be used in the next group of tests (Group 2), as the storage in the ice-box might have destroyed some of the active material. However, when the fresh gastric juice was used, no reticulocyte responses followed the injection on three occasions of the portion of the fresh gastric juice held back by the ultrafilters, and on one occasion

* A potent preparation obtained by the interaction of liver or liver extract with hog gastric tissue.

the ultrafiltrate after it was concentrated by vacuum distillation. Chart II (Case 4) is an example of the results in this group.

Morris and his associates reported maximal responses of the reticulocytes following the injection of similar amounts of gastric juice after concentration by vacuum distillation, and yet we obtained only slight responses

CHART I.—The response of the blood of Case 1 to two intramuscular injections of human gastric juice that had been stored in the ice-box for two months before being concentrated by ultrafiltration, and to the oral administration of extralin capsules 4, three times a day.

when the gastric juice which had been stored in the ice-box for two months was concentrated by ultrafiltration and injected, and no responses when the fresh gastric juice was concentrated by ultrafiltration and injected. To test whether the concentration by vacuum distillation

had caused some change in the fresh gastric juice, it was decided to subject the latter to concentration by vacuum distillation before using the ultrafilters (Group 3). Case 6 was injected with gastric juice concentrated by vacuum distillation only. A maximum reticulocyte response (11.2 per cent. at a red blood cell level of 1.82 millions), and a satisfactory rise in red blood cells followed. No further reticulocyte rise followed extralin therapy. Four patients received injections of gastric juice first concentrated by vacuum distillation, then diluted with distilled water, and re-concentrated by ultrafiltration. Definite reticulocyte rises followed all of these injections. The reticulocyte rises were 9.8, 8.7, 8.2, and 2.8 per cent. when the red blood cell levels were 0.7, 3.25, 1.91, and 2.7 millions, respectively. The reticulocyte peak of 8.7 per cent. in Case 8 was apparently maximal, as no further rise in reticulocytes followed the injection of liver extract intramuscularly.

Case 11 had previously responded to the concentrated ultrafiltrate, and the 2.8 per cent. response, followed by a rise in red blood cells, was considered quite satisfactory. The two other responses were not maximal, as subsequent treatment produced additional reticulocytoses.

Case 11 received intramuscularly the portion of the gastric juice concentrated by vacuum distillation that

CHART III.—This shows the response of the blood of Case 11 to the intramuscular injection of the portion of the fresh human gastric juice concentrated by vacuum distillation that passed through the ultrafilter (1), and to the portion of the fresh human gastric juice concentrated by vacuum distillation and then re-concentrated by ultrafiltration (2).

passed through the ultrafilters. This ultrafiltrate was concentrated by vacuum distillation before injection. Chart III shows the marked and prolonged reticulocytosis. Evidence of bone marrow stimulation (many nucleated

red blood cells, myelocytes, and nuclear particles) appeared at the onset of the greatest rise in reticulocytes. Case 7, in which there had been nine previous responses to liver extract, received a similar preparation. The patient was in cardiac failure when injected. By the seventh day the reticulocytes had started to increase, but the cardiac failure had not responded to medication, and the patient developed bronchopneumonia and died. After each injection in this group there was some type of reaction, the severest

CHART II.—The response of the blood of Case 4 to the intramuscular injection of fresh human gastric juice concentrated by ultrafiltration only, and to the weekly intravenous injection of the amount of liver extract derived from 100 grams of whole liver.

following the injection (Case 11, first injection) which caused the greatest reticulocytosis. The clinical response of each patient was proportionate to the height of the reticulocyte responses.

The results in the three groups of observations indicated clearly that some change in the gastric juice had taken place during the process of vacuum distillation. However, in Group 2 the ultrafiltrate of fresh gastric juice had been

concentrated by vacuum distillation, and no haematopoietic activity had been demonstrated. It was therefore assumed that the material in the gastric juice that could be made active by vacuum distillation was held back by the ultrafilters. To test this, Case 12 was injected with fresh gastric juice first concentrated by ultrafiltration, then diluted with 0.3 per cent. hydrochloric acid, and reconstituted by vacuum distillation. The patient had a severe reaction, a decrease in red blood cells, and an increase in icterus following the injection. Chart IV

CHART IV.—This shows the prolonged reticulocyte response of Case 12 following the intramuscular injection of normal human gastric juice first concentrated by ultrafiltration, then diluted and reconstituted by vacuum distillation, and the response of the blood to three intramuscular injections of the amount of concentrated liver extract (3 c.cm.) derived from 100 grams of whole liver.

shows the prolonged reticulocytosis, the peak (345,000 per c.mm.) being reached on the thirty-fifth day after the injection. A definite clinical response and rise in red blood cells had occurred by then, although the rise in red blood cells was markedly delayed. There was a subsequent increase in reticulocytes following the intramuscular injection of liver extract.

This showed conclusively that the material in the gastric juice which could be made active was held back by the ultrafilters used. It also demonstrated that the gastric juice concentrated by ultrafiltration and reconstituted by vacuum distillation was haematopoietically active, whereas on three occasions (Group 2) the gastric juice concentrated by ultrafiltration only had been inactive. The results obtained in Group 3 and in Case 12 indicated that after concentration by vacuum distillation a goodly percentage of the activity passed through the ultrafilters, although practically all of the material that could be released or made active by concentration by vacuum distillation was held back by the ultrafilters. It would seem, therefore, that during the process of vacuum distillation a haematopoietically active substance was obtained that was smaller in size than the material from which it was formed or released.

SUMMARY

The results of these studies indicate that some change in fresh human gastric juice must take place before a haematopoietically active material can be demonstrated by the intramuscular injection into patients with pernicious anaemia. At the present time the actual mechanism of this change is not known. Any of at least three explanations might account for this change. The first is that, during the process of vacuum distillation the intrinsic factor acts upon an extrinsic factor present

in the gastric juice in too small amounts to be active when fed by the mouth. The intrinsic factor is known to be present in fresh human gastric juice, and has been demonstrated by us in another group of experiments to be present at the onset of the vacuum distillation in all the preparations which were made active by this procedure, and in none of those that were not so made active. The second is that during the process of concentration by vacuum distillation, a material irritating or toxic to the haematopoietic system is produced. The prolonged and delayed reticulocyte response, marked bone marrow irritation, the delayed rise in red blood cells, and the fact that each patient who responded to the injection of the concentrated gastric juice had a more or less severe reaction, suggest this possibility. Case 12 is of especial interest in this connexion. After the injection the temperature rose to 106° F., the red blood cell count decreased 0.55 million, and there was an increase in icterus. There was no rise in red blood cells until after a prolonged reticulocytosis. The third possibility is that during the concentration by vacuum distillation a hormone is released or activated.

In our opinion the haematopoietically active substance must be formed by the action of the intrinsic factor on an extrinsic factor in the gastric juice, or by the production of a substance irritating or toxic to the haematopoietic system.

ADDITIONAL SYMPTOMATOLOGY IN SIMPLE ACHLORHYDRIC ANAEMIA

BY

A. W. VAISEY, M.B., B.CHIR.CANTAB.

LATE HOUSE-PHYSICIAN, ST. THOMAS'S HOSPITAL MEDICAL UNIT

Although its recognition has been slow, its nomenclature varied, and its features diverse, unequal, and inconstant, a type of non-haemolytic primary anaemia, associated with a relative gastric achlorhydria, has of recent years been admitted a separate clinical entity since its distinctive pathology was made clear by Witts' in the Goulstonian Lectures of 1932. The object of this communication is to indicate two additional features of the symptomatology, believed not to have been hitherto recorded, which occurred in patients admitted to St. Thomas's Hospital Medical Unit during 1932. These are: (1) acne rosacea, and (2) thinning of the hair. It must be admitted in each case that a single example of such a symptom might appear at first sight to have occurred fortuitously, in spite of the diversity of symptoms—more especially abdominal—which are known to occur; but it is considered justifiable to record them, if only because they might be expected on pathological grounds.

ACNE ROSACEA

The skin condition was observed in a woman with most of the usual features of simple achlorhydric anaemia.

Mrs. G., aged 60, complained of palpitations and shortness of breath for six months, accompanied by pain in the epigastrium, chiefly post-prandial. She had long come to

recognize that meat in any form particularly aggravated the pain, and for some weeks she had been subsisting mainly upon carbohydrates. On examination there was slight oedema of the ankles and moderate enlargement of the spleen. The blood contained 4.3 million red cells per c.mm., but only 32 per cent. haemoglobin, and the stained films showed poikilocytes and occasional pessary forms. Gastric content analysis revealed no free HCl to histamine stimulation in half-hourly specimens up to two and a half hours. Considered together, the symptoms gave no doubt as to the clinical condition. But in marked contrast to the considerable pallor of the rest of the skin, that of the nose and cheeks was blotchy and hyperaemic, with a downward spread also on to the lower lip. This blotchy area consisted of confluent papules, which were not, however, surmounted with comedones, and even a casual inspection made it certain that the condition was typical acne rosacea.

The interest of this case lies in the fact that acne rosacea has long been known to be associated with some form of alimentary disturbance. As long ago as 1920 Ryle and Barber² made gastric analyses in a series of twelve cases, in five of which there was complete achlorhydria throughout the period of the meal, while in two of the others there was marked hypochlorhydria. Although, it is believed, this observation has not been repeated, a degree of hydrochloric acid deficiency is now assumed by most dermatologists in the treatment of acne rosacea. The case recorded above at least indicates a common aetiological factor, since in one and the same patient there occurred two conditions—an anaemia and acne rosacea—both known to be associated with gastric hypochlorhydria, yet hitherto only separately encountered. A common factor is further suggested by the fact that the cutaneous and anaemic states improved *pari passu* under treatment. If, moreover, in apparently uncomplicated acne rosacea, blood counts revealed some degree of diminished red cell haemoglobin content, this common aetiological factor might be proved.

ALOPECIA

The case notes of the patient who complained of thinning of the hair were as follows.

Mrs. B., aged 45, had had flatulence and fullness after food for ten months, and latterly had noticed difficulty in swallowing. Most of the typical signs were present, including, incidentally, well-marked atrophy of the buccal and pharyngeal mucous membrane, on account of which difficulty was found in passing the stomach tube. On inquiry she stated that her finger-nails were very brittle and liable to longitudinal splitting: they were flat, short, and diamond-shaped, the pulp of the fingers projecting almost as far beyond each nail-tip as the total length of the nail itself. Finally, she volunteered that her hair had been "coming out" to a very considerable degree in the past six months. The diagnosis of simple achlorhydric anaemia was made, but as her hair was certainly thin and brittle it was at once recognized that a determination of the basal metabolic rate was indicated in view of the possibility of a superimposed early myxoedema. This, however, was found to be within normal limits.

Nail changes, well exemplified in the case above, are fairly common in this type of anaemia, but the pathology is obscure, since they are not found in other anaemic states, primary or secondary. No mention, however, is made in the literature of thinning of the hair. But as hair resembles nail substance, in consisting essentially of modified horn cells, it is suggested that the same unknown factor is responsible for both nail and hair dysfunction in the simple achlorhydric type of anaemia, presumably depending on iron deficiency.

I am indebted to Professor O. L. V. de Wesselow, under whose care they were admitted, for permission to publish these cases.

CIRCUMCISION AND SYPHILIS

BY

V. E. LLOYD, M.B., B.S.

DIRECTOR, VENEREAL DISEASES DEPARTMENT, GUY'S HOSPITAL
AND

N. L. LLOYD, M.B., M.R.C.P.

LATE MEDICAL OFFICER, VENEREAL DISEASES DEPARTMENT,
GUY'S HOSPITAL

The hygienic value of circumcision in the male infant has been generally acknowledged over a very long period. All will agree that such conditions as acute balanoposthitis and carcinoma penis are seldom, if ever, seen in the circumcised. It is also commonly believed that the incidence of syphilis is considerably lower in circumcised persons. In view of this widespread belief it is somewhat surprising that so few statistical reports bearing on the incidence of acquired syphilis in circumcised and non-circumcised males should be available.

There appears to be little information on this subject, particularly since the introduction of the more accurate methods in the diagnosis of syphilis following upon the discovery of *Spirochaeta pallida* and the utilization of the Wassermann test.

Jonathan Hutchinson,¹ on reviewing his cases for the year 1854, stated:

"Notwithstanding a gross proportion of nearly one-third to others the cases of syphilis presented by Jews are only as one to fifteen. That this difference is not to be accounted for by their superior chastity or their unwillingness to seek medical aid is conclusively proved by the fact that they furnish very nearly half the cases of gonorrhoea. The circumcised Jew is, then, very much less likely to contract syphilis than an uncircumcised person."

Hutchinson's figures are shown in Table I.

TABLE I—Veneral Cases (1854)

Total Venereal Cases	Gonorrhoea	Syphilis	Proportion of Gonorrhoea to Syphilis
Non-Jews, 272	107	165	0.6 to 1
Jews, 58	47	11	4.3 to 1

Feldman² refers to the male venereal out-patients at the Metropolitan Hospital during the year 1882-3, among whom syphilis was present in 17.8 per cent. of the Jews and 62 per cent. of the non-Jews. Assuming that the remaining patients were suffering from gonorrhoea, these figures give the proportion of gonorrhoea to syphilis in Jews as 4.5 to 1 and in non-Jews as 0.6 to 1. These proportions are almost identical with those found by Hutchinson (Table I) at the same hospital some thirty years earlier.

Breitenstein³ reported in 1902 observations on 15,000 native circumcised soldiers and 18,000 European soldiers in the Dutch Indies. He noted a greater proportion of venereal infections in the non-circumcised, and that syphilis in particular was much more frequent in the non-circumcised troops.

Wollbarst⁴ has reported upon venereal diseases in the circumcised and non-circumcised, utilizing 800 cases under his care. He found that in 400 circumcised patients the proportion of syphilis and soft chancre combined was 22 per cent., whereas in 400 uncircumcised patients the proportion of syphilis and soft chancre was 41 per cent. Unfortunately this author does not give the separate figures for syphilis and for soft chancre.

More recent figures were given in 1928 by Berkowitsch,⁵ who recorded the incidence of venereal diseases in Jews

and non-Jews. He found that, while the incidence of gonorrhoea was much the same in the two groups, syphilis was twice as frequent among the non-Jews, and soft chancre was six times as common. The total number of cases of syphilis observed was small. (See Table II.)

TABLE II.—Venereal Diseases in Jews and Non-Jews

Total Questioned	Syphilis		Gonorrhoea		Soft Chancre	
	No.	Per cent.	No.	Per cent.	No.	Per cent.
Jews, 1,323	15	1.13	175	13.2	6	0.45
Non-Jews, 1,434	31	2.5	222	15.4	39	2.7

The deductions concerning the frequency of syphilis by several of the authors quoted were based on the proportion of Jews and non-Jews, and not directly on the circumcision or non-circumcision of the individual. No consideration appears to have been given to the possible inclusion of circumcised individuals in the non-Jewish group. As is well known, circumcision is not uncommon among non-Jewish races. The probable inclusion of a certain and by no means negligible number of circumcised persons in the non-Jewish group detracts somewhat from the accuracy of these analyses. Wolbarst,⁴ whose analysis is one of the few based on circumcision and non-circumcision, and not upon racial differences, unfortunately includes syphilis and soft chancre in the same group, and the actual number or proportion of cases of syphilis is not ascertainable from his figures.

In view of these deficiencies it is considered that some information on this subject from present-day material in this country will be of some interest.

PERSONAL OBSERVATIONS

This analysis concerns observations made upon new male cases attending the department for venereal diseases at Guy's Hospital from January to June, 1932. These patients were, in the majority of cases, suffering from venereal disease, but a proportion were not so suffering, and it has appeared to us to serve a useful purpose to consider these additional cases. All cases of congenital syphilis and of extragenital syphilitic infection have been excluded from this series.

The records of 499 patients who attended during the period stated are available for the purpose of these observations. These patients have been considered not only as regards the present venereal condition, but also as regards previous venereal disease when the history appeared accurate. For example, a patient who had acquired syphilis ten years ago and who now has gonorrhoea is considered under the heading of both diseases, a patient giving a history of gonorrhoea five years ago in which the diagnosis was subjected to microscopical control is considered under the heading of gonorrhoea.

Under the heading of two venereal diseases twenty-nine patients are included, while one patient suffered from soft chancre in addition to gonorrhoea and syphilis; 130 patients were not suffering from, and gave no history of previously suffering from, any venereal disease. Of those with an active venereal condition or a reliable history of previous venereal disease there were 369 cases. Some of these, as already stated, were suffering from more than one venereal disease, and the total number of infections for inquiry amounts to 400. Including those free from venereal infection the total is 530. These 530 conditions occurred in the following proportions:

Syphilis	112
Gonorrhoea	278
Soft chancre	10
Non-venereal disease	130

The totals of these various groups are in the same proportions as have existed among patients attending this department during the last few years. The 499 patients who are considered here fall into the following groups: circumcised, 118; non-circumcised, 381. In any large group of uncircumcised men a small proportion will be found in whom the prepuce is in a condition of phimosis. A small proportion will also be found in whom the prepuce is naturally short and is normally retracted, so that the glans penis is habitually exposed; in others there is a well-marked but short fold of skin around the corona glandis (in some of these the prepuce is almost rudimentary). It is suspected that some of these patients had undergone an incomplete circumcision in infancy.

These departures from the average anatomical condition of the prepuce seem to warrant a separate category in the present analysis. In the following tables the term "short prepuce" includes those cases where the prepuce appears rudimentary and where there exists a short prepuce with a permanently exposed glans penis. The anatomical condition of the prepuce in the 499 patients was as follows:

Circumcised	118 or 23.6 per cent.
"Short prepuce"	61 or 12.0 "
Average prepuce	300 or 60.0 "
Phimosis	20 or 4.0 "

The diseases associated with these preputial states are shown in Table III.

TABLE III.—Anatomical State of the Prepuce in Relation to Venereal Diseases

	Syphilis	Soft Chancre	Gonorrhoea	Non-venereal Conditions
Circumcised	25	1	75	24
"Short prepuce"	15	0	30	17
Average prepuce	68	8	156	77
Phimosis	3	1	7	12

The number of cases of phimosis is too small to provide information of value. It is, however, noteworthy that of the twenty cases a little less than one-half were suffering from venereal disease, a proportion that is considerably lower than that for the remaining anatomical groups. The high proportion of non-venereal conditions in this group was due to the occurrence of acute balanitis in many of the cases.

The number of cases of soft chancre is also too small to be subjected to analysis; this condition was present in only one of the circumcised patients, and in no case in the smaller group with a "short prepuce." Soft chancre occurred once in the 179 patients who had been circumcised or with a "short prepuce," and nine times in the 320 patients (1 in 35) with a prepuce of average extent or with phimosis. This is in keeping with the usual teaching on the relation of circumcision to soft chancre. Disregarding the cases of soft chancre for the reason given, the preputial states found in the various diseases have been analysed and compared, and are shown in Tables IV, V, and VI.

TABLE IV.—Anatomical State of the Prepuce of 112 Patients with Syphilis

	No. of Cases of Syphilis	Per cent.
Circumcised	25	22.3
"Short prepuce"	16	14.3
Average prepuce	63	60.7
Phimosis	3	2.7

TABLE V.—*Anatomical State of the Prepuce of 278 Patients with Gonorrhoea*

	No. of Cases of Gonorrhoea	Per cent.
Circumcised	75	27
"Short prepuce"	30	10.8
Average prepuce	166	60
Phimosis	7	2.5

TABLE VI.—*Anatomical State of the Prepuce of 130 Patients with no Venereal Disease*

	No. of Patients	Per cent.
Circumcised	24	18.4
"Short prepuce"	17	13.0
Average prepuce	77	59.2
Phimosis	12	9.2

So far there appears to be no striking difference in the relative proportions of the various anatomical divisions of the prepuce in the three groups. Circumcision is noted a little more frequently in the cases of gonorrhoea than in those of syphilis and a little less frequently in the non-venereal group.

A comparison of the distribution of the various classifications of the prepuce in the syphilis group with that of the whole group of the 499 patients under observation reveals an extremely close similarity. (See Table VII.)

TABLE VII.—*Anatomical State of the Prepuce of the Syphilis Group Compared with the Whole Group*

	Syphilis Cases, Total 112	Whole Group, Total 499
Circumcised	22.3 per cent.	23.6 per cent.
"Short prepuce"	14.3 "	12 "
Average prepuce	60.7 "	60 "
Phimosis	2.7 "	4 "

When we compare the syphilis rate in the 118 circumcised patients with that of the non-circumcised group of 381, we again find that there is no difference of any significance—namely, 20.2 per cent. in the circumcised group compared with 21.9 per cent. in the non-circumcised group.

We have already indicated that a prepuce that is very short or is rudimentary in extent is by no means uncommon among these patients. If the number of such patients is included among the circumcised, we have a composite group of patients in whom the prepuce has either been removed or is naturally extremely deficient, and in whom the glans penis is permanently exposed. The syphilis rate of this composite group compared with that for the remaining patients in whom the prepuce is of average extent or phimotic is shown in Table VIII; the figures indicating the syphilis rate are almost identical.

TABLE VIII.—*Syphilis Rate in (A) Circumcised Patients and others with Permanently Exposed Glans, compared with (B) Patients with an average Prepuce or Phimosis*

	Total Number of Patients	No. of Cases of Syphilis	Percentage of Cases of Syphilis
Number circumcised or with "short prepuce"	179	41	22.9
Number with average prepuce or phimosis	320	71	22.2

CONCLUSION

The total number of cases in this series is small in comparison with the large groups reported by others—for example, Breitenstein.³ Attempts have been made to make up for this deficiency in numbers by greater accuracy in recording the anatomical condition of the prepuce and not relying upon racial classifications. It is probable that any large group of non-Jewish men will contain some who have been circumcised. A considerable number of men in the circumcised group of our series were not of Jewish faith. Also it appeared to us that the inclusion of a separate group for cases with a deficient prepuce is productive of some interest and value.

From the results of analysis of our cases it appears that the absence of the prepuce is not the important preventive factor in the acquisition of syphilis that is commonly believed.

Memoranda

MEDICAL, SURGICAL, OBSTETRICAL

TRAUMATIC DETACHMENT OF RETINA:
OPERATION: RECOVERY

In view of the great interest aroused during recent years in the operative treatment of this condition the following case appears worthy of record.

F. C., male, aged 42, attended the casualty department of the Princess Beatrice Hospital on March 3rd, 1932.

History and State.—While he was chopping wood a piece flew up and struck him a violent blow on the right eye. He complained of misty vision and seeing double with the injured eye. He was given local treatment. When referred to me a few days later the affected eye was found to be bandaged and the pupil dilated with atropine. The margin of the pupil was dentated, showing that some fibres of the ciliary muscle were ruptured. At the time of my examination there was no hyphaema. Vision of the injured eye was 5/24, not improved. Vision of the left eye with -4 D sph. = 5/5. He had never worn glasses, and told me that the injured eye was always his good one, and that he relied on it chiefly for his work as a skilled repairer of antiques. On ophthalmoscopic examination he was found to have a detachment of the retina in the upper and outer quadrant. No tear of the retina could be seen. Local treatment—that is, atropine with bandage—was continued pending his admission to hospital. He was admitted as an in-patient on March 21st, 1932. By this time, however, it was noted that the detachment had definitely become more extensive, and had gravitated into the lower and outer quadrant. In hospital he was kept flat in bed, with both eyes bandaged, the use of atropine in the injured eye being continued. He was examined again after three days, but as the detached retina appeared to be losing transparency and showed no signs of spontaneous improvement from recurrent treatment it was decided to operate forthwith.

Operation (March 24th, 1932).—The patient was placed on the table and the eye cocaineized. With the speculum introduced, the conjunctiva and Tenon's capsule were dissected back from the globe between the inferior and external recti and held back with a retractor by my assistant. The meridian of maximum detachment appearing to be at "8 o'clock," a point was stained with methylene-blue 7 mm. from the corneal limbus to mark the approximate position of the ora serrata, and another point selected on the same meridian 4 to 5 mm. further back. At this spot a hole was made through the sclerotic and choroid with a pointed electro-cautery heated to a bright red. The subretinal fluid oozed out with a speck of vitreous. When the flow had ceased, after a minute or two the cautery was again heated to whiteness and pushed

through the hole to a depth of 2 mm., but only for a moment. No surface cauterization of the sclera in the vicinity of the puncture was done. The conjunctival stitches were inserted, atropine instilled, and both eyes bandaged. The patient remained in bed for only five days, when the stitches were removed and he was discharged from hospital (April 1st). Just previous to his leaving hospital the eye was quickly looked at and the retina noted to have regained attachment, but no prolonged examination was made. The patient stated, however, that the sight of the eye had much improved. He was given atropine, and advised to keep the eye bandaged.

Progress.—A week later he came to the out-patient department, when the vision of the injured eye was found to be 5/6, partly, and the field, charted on the perimeter, full. He attended once a week for a month, the eye still under atropine, but after the first fortnight the bandage was replaced by a shade. As he was anxious to return to work the atropine and shade were now discontinued and permission given to resume his employment. At my request he came to see me at the hospital on September 26th—that is, over six months after the accident—when the sight of the operated eye was found to have improved to nearly 5/5. With a correction of slight myopic astigmatism in this eye he got full normal vision. The field was again charted, and noted to be full. With the ophthalmoscope the site of the cautery puncture was easily seen as a circular area about a disk-breadth diameter in the "8 o'clock" meridian, dead white, and having a margin of pigment. No creasing of the retina or vitreous opacities were detected. The patient volunteered the statement that the operated eye had become, as formerly, his better eye, and that he could see with it as well as ever. Seen again as recently as May 23rd of this year, when he was shown at a Kensington Branch meeting of the British Medical Association, held at the Princess Beatrice Hospital, the vision and field of vision of the operated eye were found to have remained normal. The cure may therefore be regarded as permanent.

The procedure adopted was on the lines advocated by Gonin, and the aim underlying this and other diathermic methods is to produce, after evacuation of the subretinal fluid, an area, or areas, of agglutinative inflammation which will tack down the detached retina to the subjacent choroid and sclerotic. A very good account of Gonin's work—and indeed of the whole subject—with bibliography, is available to the practitioner in Anderson's *Detachment of the Retina*.

The excellent result obtained in this case points to the desirability of early operation as opposed to expectant treatment of this condition, since, as is well known, the prognosis becomes progressively less favourable with the lapse of time. When, indeed, the detachment becomes total—as partial detachments ultimately tend to—no operative procedure is likely to be of any avail.

A. S. WORTON, M.D., F.R.C.S.,
Ophthalmic Surgeon, Princess
Beatrice Hospital.

CIRROID ANEURYSM OF THE SCALP

The interesting account of a case of cirroid aneurysm of the scalp, which Mr. R. A. Kerr contributed to the *British Medical Journal* of September 23rd, 1933 (p. 566), prompts me to record my experiences with such a case with which I was closely associated some twelve years ago, while acting as house-surgeon to Mr. Donald D. Day at the Norfolk and Norwich Hospital, Norwich.

Our patient was a man of about 45, who had had the tumour on his scalp for as long as he could remember; he sought medical aid on account of the fact that during the previous two years the "lump" had more than doubled its size.

On examination he presented a smooth tumour, about 4 by 2 inches, with the long axis directed antero-posteriorly, which was situated about 3 inches above the base of the right mastoid process. It presented all the signs of a typical cirroid aneurysm, and was fed by numerous strongly pulsating

vessels all round its periphery. Operation was decided upon, and with Mr. Day's assistance I ligated both occipital and both superficial temporal arteries, exposing each through a small incision, ligating in two places, and cutting between. All the obvious feeding vessels around the circumference of the tumour were similarly dealt with. This procedure, however, had little apparent immediate effect on the aneurysm, so the patient was returned to bed with a firm pad compressing the tumour, with the hope that the combined effect of partially cutting off the blood supply and of pressure would cause thrombosis. In this we were disappointed, for our activities had little or no effect; the tumour was as large, and the pulsation as active, as ever.

A fortnight later Mr. Day adopted another procedure. A thin skewer was inserted through the scalp some distance from the margin of the tumour, and at right angles to its long axis; the skewer was passed down to the pericranium, and was then pushed along the surface of the skull below the aneurysm, and made to emerge through the scalp some distance on the other side of the pulsating mass. Two other skewers were inserted in the same manner, parallel to the first, with about one inch between each. A double silkworm-gut ligature was then passed with very firm tension in figure-of-eight fashion over the projecting end of a skewer, in such a way as to indent deeply the surface of the aneurysm, and similar strands were passed round the other skewers. The aneurysm now presented a markedly lobulated surface, with a deep depression corresponding to the position of a ligature over each skewer. A sterile dressing was applied and the patient returned to bed.

Four days later the area was dressed, and in about ten days the silkworm-gut strands were cut off and the skewers extracted. The result was surprising: the aneurysm was now replaced by a hard, non-pulsating, lobulated mass, and the numerous feeding vessels round about had entirely disappeared.

The patient was discharged, and, being highly delighted with the result, co-operated with us to the extent of reporting every month; in this way I was able to witness the gradual disappearance of the tumour, and when I last saw him, nine months after the second operation, the aneurysmal mass was represented by a hard nodule about the size of a hazel nut, and the scalp surrounding it was normal. It was a striking example of the originality of thought, simplicity of technique, and satisfactory result which characterized the work of that fine old surgeon.

Norwich.

A. G. SMITH, M.D., F.R.C.S.

Reports of Societies

TREATMENT OF MUCOUS COLITIS

A meeting of the Section of Physical Medicine of the Royal Society of Medicine was held on January 19th, when the subject for discussion was the treatment of mucous colitis. Dr. M. B. RAY presided.

Dr. A. F. HURST said that specialism in therapeutics had dangers perhaps even greater than specialism in other branches of medicine, and this was illustrated by the condition of what was commonly called mucous colitis. Such a case might for months be treated with vaccines, or intestinal lavage, or possibly diathermy, when all the time the so-called mucous colitis was nothing else than achlorhydric gastritis, which could be cured with a few doses of hydrochloric acid; or, alternatively, it was something much more serious, a carcinoma of the colon, which during the time of treatment had passed from the stage of safe operation to that of complete inoperability. In his own view there was no such thing as mucous colitis. The colon, like every other mucous membrane, had as one of its important functions the secretion of mucus in order to protect itself from injury. The injury might be either mechanical or chemical irritation. Mechanical irritation occurred in inefficient defaecation, when impaction of faeces irritated the mucous

membrane, and the colon, to protect itself, secreted an excess of mucus. If the mucus were examined in a case of that kind it would be found to contain no leucocytes, no red corpuscles, and no abnormal bacteria, and examination by the sigmoidoscope would reveal no inflammation of the mucous membrane. As for chemical irritation, this was most commonly caused by aperients. It was caused also by almost every form of enema, especially soap enema. The only fluid which produced no secretion at all was normal saline. In many cases spa treatment, when carefully given and when the water was isotonic, produced little or no irritation, and there was no excessive secretion of mucus. The discovery of mucus in a patient who had had a douche or enema of any kind was no evidence of colitis; it was simply the response of the normal mucous membrane to the action of the enema. Another cause of chemical irritation, too little realized, was found in patients with achlorhydria which resulted from chronic gastritis. Here the food passed too rapidly through the small intestine and reached the colon in a chemically and mechanically irritating form, undergoing bacterial decomposition there. If all these causes were excluded the number of patients who passed mucus was extremely small; it was a very unusual condition. Mucous-membranous colitis, formerly very common, had become more and more rare; he did not know why it had almost completely disappeared. A better name for true mucous-membranous colitis would be mucous-membranous colic. The condition of colon spasm with or without mucus was a reaction to an abnormally irritable sympathetic nervous system; it was a neurosis in the sense that it had no organic basis. He had known mucous colitis diagnosed because a patient was suffering from so-called intestinal auto-intoxication. He did not believe there was such a thing as auto-intoxication from the colon; at least it was very rare. The vast majority of patients who were suffering from true intestinal auto-intoxication were suffering from treatment for constipation—that is to say, they were taking purgatives. Under normal conditions hardly any decomposition went on in the colon at all; on the other hand, if purgatives were taken, both protein and carbohydrate food was rushed through the small intestine and reached the caecum in an undigested condition, and there the toxins were absorbed. As for conditions of the colon which were really amenable to physical treatment, what he had already described as colon spasm very often benefited, particularly if there was no organic condition such as a diverticulitis; and another large group of patients who benefited by physical treatment were those who came back from the Tropics having had some intestinal infection which had completely died out but had left them with uncomfortable and abnormally irritable colons. One special form of physical treatment which he had himself found of particular value was the treatment of the anal canal by means of local diathermy, using a conical electrode.

Dr. GEOFFREY HOLMES said that mucous colitis, termed "mucous colic" by some American writers, was generally thought to be a secretory neurosis. Few necropsies on this condition were recorded, but where there was simply hypersecretion of mucus no inflammatory condition was found in the colon. More frequently it was associated with a catarrhal condition, the site of which varied, and to indicate this Dienlaofo used the phrase "mucous, membranous, and sabulous entero-typhlo-colitis." The acute and chronic stages called for different treatment. In the early acute stage, warmth, rest, and bland diet, with the administration of bismuth and brounide or salol and belladonna, were often effective. In the chronic forms intestinal lavage would often hasten a cure. It had been said that intestinal lavage was more likely to cause than cure colitis; whilst this might be true when irritating substances, such as soap and turpentine, were used in enemas, or when the technique of administration was faulty, intestinal lavage carefully given with warm isotonic natural waters and followed by immersion baths with hyperthermal undercurrent douching was most beneficial. He proceeded to describe the use of Harrogate waters in mucous colitis. At Harrogate the great majority of the cases were treated with the spa waters. Abdominal packs were also employed, and almost any pack was a remedy

for relief of abdominal pain and spasm. Harrogate sulphur water had a helpful aperient action. It was for intestinal lavage that the Harrogate waters were most useful. His own experience did not bear out Dr. Hurst's view that the condition was becoming rarer.

Dr. JULIUS BURNFORD said that whether or not mucous colitis was becoming rarer, other varieties of inflammation of the colon seemed to him to be more and more frequent. These could be summed up in the term "ulcerative colitis." Was mucous colitis a preceding stage of catarrhal, granular, or more definitely ulcerative colitis? Experience rather suggested that it was in no way allied to the inflammatory group. Anatomical factors were lacking, and those who were concerned with mucous colitis had not the opportunity of the pathologist or of the surgeon to lay down any anatomical basis for the condition that they tried to define as mucous colitis or mucous colic. They were compelled, therefore, to argue from symptoms, and deal empirically with them. The first duty was to relieve symptoms and then to question the aetiology. The spasm he had never found to disappear under belladonna; nothing short of morphine had any effect. For the constipation he had always preferred to fall back on the old-fashioned treatment of castor oil, with laudanum to relieve the spasm. But the crux of the whole problem was the abuse of the bowel by purgatives. With regard to enemas, he expressed very strong views against colon lavage. He had had patients return to him after months of colon lavage, with no permanent benefit whatever, only some temporary comfort at the time the lavage was applied. What treatment, then, should be recommended for the relief of the patient? In the first place he thought that the question of diet needed careful investigation. His own experience was that the faulty article in the diet primarily was the starch. The diet must be bulky, and hence one would prefer to obtain the proteins in a diluted form, preferably from vegetables, and at the same time to give the colon what it was demanding—namely, the necessary bulk. He had not hesitated in his own cases of ulcerative colitis to give from the first highly vegetarian and roughage diet. Of secondary importance to the diet was physical treatment in the shape of abdominal exercises directed to the development of the musculature of the body and the repair particularly of the abdominal muscles.

Dr. E. I. SRRIGGS said that mucous colitis—and he believed it to be at all events a clinical entity—was due to two things—namely, constipation, and the regular use of aperients to cure that constipation; and the second was a more frequent cause than the first. He gave some figures showing that the incidence of mucous colitis among the people who had constipation and took aperients was more than twice as great as it was among those who had severe constipation without taking aperients. With regard to the importance of diagnosis, mentioned by Dr. Hurst, he pointed out that a reflex mucous colitis could be obtained from conditions arising somewhere else in the abdomen. Most cases of mucous colitis would bear fairly well a rough diet—that is, salads and fruits. If they would not bear it, they must be given a bland diet. Dr. KERR RUSSELL said that in mucous-membranous colic there was definitely a spasm of the bowel musculature, and it was well known that spasm could be relieved by heat. He thought, therefore, that irrigation with a hot solution was likely to give relief to the spasm as well as to assist mechanically the clearing out of the bowel. Dr. Hurst had mentioned the value of diathermy in rectal conditions, and in diathermy again the essential factor was the production of heat. Dr. G. B. BATTEN recalled the fact that about thirty-five years ago he and others were asked by Dr. (now Sir) William Hale-White to make an investigation of the treatment of what was still called mucous-membranous colitis, and to try high-frequency among other treatments. He himself had been carrying out high-frequency treatment since 1896, partly by long sparks on the abdomen and partly by the rectal application of a glass electrode, and was gratified to find that not only was it useful for the treatment of haemorrhoids, but it also relieved constipation and the insomnia associated with it. Since diathermy had been available he had frequently employed this method, with very beneficial results.

DIFFERENTIAL DIAGNOSIS OF PREGNANCY

At a meeting of the Liverpool Medical Institution on January 11th, with the president, Dr. H. R. HURTER, in the chair, Professor A. LEYLAND ROBINSON and Mr. M. DARTON presented a paper on "The Differential Diagnosis of Pregnancy."

The personal, social, and legal reasons for which the recognition of pregnancy might become a matter of urgency were described and discussed. The scope of the differential diagnosis was indicated and the value of the available clinical methods considered. It was shown that all the physical signs and symptoms might be obscured by disease or simulated by non-pregnant states, and that in all complicated cases clinical methods alone might be unable to determine the issue even in late pregnancy. Radiology was a decisive method from the fourth month onwards, but could afford no help before the sixteenth week of gestation. In the early weeks of pregnancy there was great need for a method by which the presence or absence of pregnancy could be decided with absolute certainty. A number of the oldest tests devised for this purpose were described, and attention was drawn to the fact that many of them were dependent upon reactions obtained from the urine of pregnant women. The history of the modern biological tests was related, and the modified Aschheim-Zondek test which was being carried out at the Pregnancy Diagnosis Station in the University of Liverpool, was described. The results obtained were discussed. Out of a total of 706 tests 373 had been positive and 333 negative. There were three wrong results in the positive group and ten in the negative. Modified reactions were obtained with 170 specimens of urine obtained from patients at the menopause, from women after castration, and from others who were in process of abortion. These results were correlated with the changes in the type and concentration of the hormones present in the specimen, and they afforded valuable help in the differentiation of certain clinical conditions that were liable to be confused with pregnancy. Lastly, the authors described the hormones responsible for the test, and illustrated their biological action by means of lantern slides and specimens.

Dr. J. W. BURNS said that the value of the Aschheim-Zondek test depended largely upon the individual who carried it out, the methods which he adopted, and the standard to which he worked. There was no doubt that the test had been made more valuable by the way in which it was carried out in the Liverpool Pregnancy Diagnosis Station. The test was by no means infallible, and should only be used as an aid to diagnosis. It was at its best when used to corroborate or otherwise the diagnosis made on the clinical evidence.

Dr. T. N. A. JEFFCOATE said that the occurrence of doubtful or incorrect Aschheim-Zondek reactions was not always the fault of either the test, the technique, or the technician. Urines for examination were frequently collected at midday; at that time the concentration of the hormones was much less than in an early morning specimen. Moreover, it was quite possible that when such a large number of tests were under consideration one or two errors might be due to faulty labelling of specimens or confusion of test animals.

Dr. J. H. WILLETT said that the test was proving a valuable aid to diagnosis in such conditions as chorion epithelioma and intrauterine death of the foetus, and he thought that continued research would lead to a further reduction in the admitted, if small, percentage of errors. The test was not intended to take the place of clinical diagnosis of ordinary pregnancy.

HOARSENESS AS A SYMPTOM

At the last meeting of the Section of Laryngology and Otology of the Royal Academy of Medicine in Ireland, with the president, Dr. P. J. DEMPSEY, in the chair, Dr. O. T. GRAHAM read a communication on "Hoarseness as a Symptom of Disease."

Dr. Graham stressed the fact that hoarseness or huskiness was merely a symptom of disease not necessarily

situated in the larynx itself but in parts so remote as the brain or aortic arch. It was a symptom that always called for prompt and thorough investigation. It might be acute or chronic, intermittent or persistent. For clear phonation the vocal cords must be able to approximate, to draw tenses, and to vibrate. Approximation might be interfered with by a tumour between the cords, feebleness of the muscular action, paralysis, or fixation; and tension by paralysis, feebleness, or fixation. Vibration might be affected by thickening of the vocal cords by inflammation, infiltration, or neoplasms; or by growth causing fixation of the vocal cord. Sometimes a functional or hysterical aphonia occurred, particularly in young female adults, where no evidence of disease was present; but here one must be on one's guard in giving a prognosis, owing to the fact that what appeared to be a functional aphonia, occurring intermittently, might be the precursor of tuberculous laryngitis.

A list of fifty possible causes of hoarseness extracted from the literature was demonstrated on the epidiascope and commented upon by Dr. Graham. As in other situations, he said, so in the larynx one of the crucial problems was whether a swelling or ulcer was due to a tumour (benign or malignant), syphilis, or tuberculosis; indeed, the patient might be suffering from all three simultaneously. In arriving at a correct diagnosis it might be necessary to go through the following steps: (1) A complete history. (2) Indirect laryngoscopy. (3) Bronchoscopy and oesophagoscopy. (4) General examination—heart, lungs, kidneys, and central nervous system. (5) X-ray—skull, neck, and chest. (6) Wassermann blood test. (7) Bacteriological examination. (8) Microscopical examination of piece of growth. An account was given of many illustrative cases of acute and chronic laryngitis, oedema of glottis, diphtheria, syphilis, tuberculosis and tumours of the larynx, and haemorrhage into the vocal cords, nervous affections of the larynx, including recurrent paralysis from aneurysm of the aortic arch, mediastinal growths, and bulbar paralysis. Some interesting cases of hoarseness due to foreign bodies in the larynx and in the oesophagus, which compressed the larynx and trachea, were illustrated by x-ray photographs, and some of the foreign bodies removed were exhibited.

Evipan in Oto-rhino-laryngology

Dr. P. J. KEOGH read a paper entitled "Some Experiences of Evipan in Oto-rhino-laryngology." He said that from a personal experience of this drug, both as a pre-anaesthetic medication and as an anaesthetic, he had come to the conclusion that in both spheres it is pleasant, rapid, and reliable. Dr. Keogh gave particulars of the dosage and technique of administration. He said that the cough reflex was present throughout anaesthesia in all his throat cases. In intranasal work a troublesome point was the preservation of a very vigorous sneeze-reflex, which could, however, be eliminated by cocaine-nazation. Comparing evipao anaesthesia with inhalatory methods, he said that in two cases he had observed a well-marked resistance to the drug, which came on after about seven to ten days, and might persist for over two months.

Dr. G. P. MELDON said that in a large experience of evipan he had come to similar conclusions to those formed by Dr. Keogh, and had observed the "sneezing reflex."

At a clinical meeting of the Ilford Medical Society, held at King George Hospital, Ilford, on January 9th, Dr. A. C. HAMPTON gave an address on the diagnosis and treatment of certain disorders of the blood. Dr. Hampton emphasized the necessity of the early and correct diagnosis of anaemias, especially in the newborn and in the pregnant mother, and stressed the grave results of an inaccurate diagnosis. He brought to the notice of the members the therapeutic value of inorganic copper and manganese salts and vitamins in the treatment of anaemias, and showed the excellent results obtained by the giving of yeast extract (vitamin B) and orange juice (vitamin C) in combination with inorganic iron. The address was followed by a discussion in which many members took part, particularly Dr. A. Pioey, who advanced his own experiences and theories.

Reviews

RADIOGRAPHY OF THE URINARY SYSTEM

The advance of radiology has been the most important single factor in the development of the diagnostic accuracy which characterizes modern urology, an advance which was equalled only in importance by the introduction of the cystoscope. In their volume entitled *Roentgenographic Studies of the Urinary System*,¹ Drs. LOWER and NICHOLS have presented what is largely an atlas of the radiological aspects of urology. The volume is large, running into 800 pages, and giving the radiological findings in 443 cases, together with brief clinical notes. The first impression one has in reading the book is one of amazement and envy at the wealth of first-class material which the authors have at their disposal; the second is that a great deal more could have been made of it had it been presented in a more scholarly and more careful fashion.

The introductory chapters are devoted to a consideration of radiological technique as applied to diseases of the urinary tract and to a brief outline of the commoner pathological conditions met with. The former of these sections is done almost entirely from the point of view of the radiologist, while that devoted to pathology is far too elementary for a volume such as this sets out to be. For example—in the account of hydronephrosis no adequate conception of the pathological basis in relation to radiological diagnosis is put forward. In connexion with the subject of pyelography in renal tuberculosis the authors begin by saying that they consider the advantages to be gained by this method far outweigh the danger encountered (presumably therefore referring to the instrumental method), since in such cases the pyelogram is practically diagnostic; they then go on to say that pyelography is indicated on the side opposite the diseased one, and conclude in a sentence of great obscurity that intravenous pyelography is the method of choice.

Radiographic studies form the bulk of the book. These are admirably produced, and include illustrations of normal and abnormal conditions in the urethra, bladder, ureters, and kidneys. The general level of the reproductions of the skiagrams is extremely high, and in this respect all concerned in the production are to be congratulated. Particularly good are those dealing with congenital malformations of the upper urinary tract. There are places where repetition and duplication of material occur, and here the sections dealing with the vesical and renal calculi may be quoted. In a book of this type there should be no place for mere repetition, and comparable skiagrams should only be included if they illustrate some point not seen in others. The section devoted to intravenous urography is very short, and the illustrations here do not come up to the level of those in the rest of the book. While the skiagrams may satisfy the most exacting radiologist, the brief notes included will not appeal to the expert urologist, for they are only too often sketchy, inaccurate, or misleading. In case 315, for example, a renal calculus is referred to in the note on the pyelogram as being in the caudal calyx, whilst actually the skiagram shows it in the renal pelvis, and the operation note describes it as being removed from that situation. Again, in a case of hydronephrosis and nephrop-tosis (No. 213), to describe the urine as containing "many red cells and a few large bacilli" is, to say the least of it, inadequate. Under the physical findings in the same case "slight rigidity of the upper part of the right ureter" is reported; this is presumably a misprint. Many other equally careless mistakes are present in the commentaries scattered through the volume.

¹ *Roentgenographic Studies of the Urinary System*. By W. F. Lower, M.D., F.A.C.S., and B. H. Nichols, M.D., F.A.C.R. London: H. Kimpton, 1933. (Pp. xviii + 812; 812 illustrations. 5s. net.)

"Size," writes one of our outstanding critics, "is an uninteresting kind of variation, to which, if the spirit is not actually insensible, it does not care to respond." Such a criticism is not without application to a book of this kind, the more so when the text needs revision, the clinical comments correction, and the total material some pruning. It is to be hoped that these defects will be remedied in any future editions in order that the really excellent skiagrams may have a more worthy setting.

MEDICAL GYMNASTICS AND MASSAGE IN GENERAL PRACTICE

Dr. Mina Dobbie, to whom we are indebted for English editions of Dr. ARVEDSON's earlier books, has now translated and edited the fourth edition of his *Medical Gymnastics and Massage in General Practice*.² This book is intended to provide the medical gymnast with information about medical and surgical disorders in such detail as will enable him to treat them with intelligence and understanding. It does not concern itself with descriptions of remedial exercises with which the gymnast at this stage is already familiar.

The opening chapter on general pathology, methods of examination, and principles of treatment is excellent, and when assimilated by the student should form a good foundation for a rational conception of disease processes and the place of massage and medical gymnastics in their treatment. That only a page should have been given to the actual treatment of fractures seems a pity when one considers that the immediate treatment of fractures by massage is increasingly practised, and the importance of good functional results is realized more than ever before.

Considerable space is devoted to diseases of the nervous system, and the information given should be particularly helpful, since massage books hitherto have tended to deal somewhat meagrely with nervous disorders. As might be expected in a book such as this, the subject of deformities is treated with competence, and the brief sections on examination and on testing mobility are singularly clear and practical. It is disappointing to find such scant reference to pregnancy and the puerperium, as in these conditions so much can be done by a wise and skilled gymnast. Instances are only too numerous where neglect of lax abdominal muscles and pelvic floor has resulted in the chronic ill-health concomitant with faulty posture and visceroptosis. When the ideal national maternity scheme is evolved, the inclusion of physical treatment to prevent and correct these maladjustments will be of inestimable value towards the ultimate well-being of the mothers. In the next edition of Dr. Arvedson's book we hope that this chapter, and that on fractures, will be brought into line with modern teaching and practice, thus giving completeness to a work regarded for over twenty years as the standard textbook in Scandinavia, and with claims for wider recognition in other countries.

HOW TUMOURS SPREAD

Up to the present there appears to have been no systematic work in existence on the *Spread of Tumours in the Human Body*. The subject is important, and Dr. RUPERT A. WILLIS's book³ bearing that title will be welcomed, the more so as he has based his work on very extensive material, and his conclusions, many of which are not in accordance with current opinions, are therefore well

² *Medical Gymnastics and Massage in General Practice*. By Dr. J. Arvedson. Translated and edited by M. L. Dobbie, M.D. Fourth edition. London: J. and A. Churchill, 1933. (Pp. 296, 8s. 6d.)

³ *The Spread of Tumours in the Human Body*. By R. A. Willis, M.D. Monographs of the Baker Institute of Medical Research, No. 2. London: J. and A. Churchill, 1934. (Pp. 340; 103 figures. 25s.)

grounded. He has summarized our present knowledge of the modes of spread of tumours, after making a critical review of the literature contained in about two thousand articles and the results of his own experience in three hundred and twenty-three cases of malignant disease. His book is divided into two sections—general and special. The former treats of the various modes of spread, the structure of metastatic growths and their modes of extension, the stroma of metastases, the relationship between tumours and nerves, the latency of primary growths, the bearing of animal experimentation, and the susceptibility of tissues to metastases. The second part treats of the secondary tumours occurring in the individual organs of the body.

Dr. Willis is extremely critical in interpreting the observations of authors, and is prepared to be regarded as iconoclastic in places; but his criticisms have a good backing of reason, and he perceives that in dealing with the subject of metastases it is needful to define our unassailable knowledge amidst a chaos of conjecture. Instances of his rejection of current views and recorded opinions are too numerous to mention, but his comments on the alleged primary endotheliomas of bone may be noticed. The classical example of multiple primary endothelioma of bone is Marckwald's case, in which almost all the bones were affected, but no primary visceral tumour was found. The diagnosis is rejected by Willis on the sufficient ground that the prostate and thyroid were enlarged, but no microscopical examination of the organs is mentioned. A similar objection is raised in regard to several other recorded cases of alleged primary endothelioma. Most of the cases may be better interpreted as metastases from undiscovered primary growths. With regard to the diffuse endothelioma of bone (Ewing's tumour) Dr. Willis, while not denying the possible existence of a primary skeletal tumour presenting the Ewing clinical syndrome, believes that further study will reveal that most of the tumours with this syndrome are metastatic in character, and he suspects that neuroblastomas will prove to be the responsible primary growths in many of the cases. He notes that of fifty-two cases classed as Ewing's tumour in the Registry of Bone Sarcoma and discussed by Connor, necropsies were done in less than one-third of the cases, and no indications are given as to how complete these necropsies were. It is interesting to note how comparatively recent is our knowledge of the true nature of metastasis. The author states that Jenner, discussing, in 1874, the conception of the embolic carriage of tumour cells, likened this to the legendary journeys of the Wandering Jew: "Many persons believe in his existence, but I have never known anyone who has seen him." A remark of Moxon's, however, at the same meeting of the Pathological Society, proves that he was already conscious of the truth: "I have repeatedly seen rectum in the liver."

DENTAL HISTOPATHOLOGY

In the preface to *Histopathology of the Teeth and their Surrounding Structures* Dr. R. KRONFELD reminds us that till but recently extracted human teeth, animal jaws, and dried human bones have formed the staple of dental research. The purpose of this book has been "to illustrate by means of human specimens the actual tissue changes that correspond to certain well-defined clinical conditions." Animal tissues have been used only to illustrate changes experimentally produced.

A short opening chapter deals with the normal dental histology, and it is interesting to note that Dieck and

Toyoc'a's account of the innervation of dentine is unreservedly accepted. The author strongly dissents from the idea that calcium can be withdrawn from the teeth to supply a general deficiency, basing his opinion on Gies's experiments in intra vitam staining of forming enamel of dogs. The rest of the book, except for short chapters on the histology of the edentulous jaw and on laboratory technique, is devoted to pathological conditions, and the author fully justifies his prefatory plea for the use of human material. Recourse has been had to animal tissues only to illustrate the effects of pressure (employed in orthodontic treatment or incidental to traumatic occlusion) on bone and soft tissues—and here human material can scarcely be expected. All else is human—many a dental pathologist will envy the author his wonderful facilities for getting human material—with a complete clinical history of the specimen. The findings in sections of root-filled teeth are of especial interest. The apical foramen of an aseptically filled root is found by the author to be entirely obliterated by new-formed cementum, and he thinks there is reasonable ground for attempting to save infected pulpless teeth. The illustrations showing epithelial attachment of a dental granuloma to a root apex, and those of a dermoid cyst in the naso-palatine canal, are striking examples of pathological research. In dealing with "pyorrhoea" the author notes that 90 per cent. of the cases are "dirt pyorrhoea," but does not explain why only the remaining 10 per cent. should be entitled to the name "pyorrhoea." Perhaps we may ask what evidence the author has of the transformation of a mesenchyme cell to a blood cell, or that "impacted teeth move with considerable force in the direction of eruption."

The book is a very valuable contribution to dental knowledge and practice, and should find a place in the library of every dental school.

GUIDES TO OPHTHALMOLOGY

Mayou's Diseases of the Eye now appears in a fourth edition, revised and largely rewritten by Messrs. FREDERICK RIDLEY and ARNOLD SORSBY. The new authors have done their work well. The 250 pages of the book present a useful summary of ocular conditions and their treatment, such as will serve the purposes of the student for qualification, and it will also be of service to some general practitioners. Methods of examination and elementary optics and refraction receive, as they should, considerable attention, and these two sections comprise one-fifth of the whole. Thereafter follow descriptions of the common disorders of the eye and their treatment in the usual order. There are short but useful chapters devoted to the eye in general disease, and to heredity in ophthalmology. In the chapter on glaucoma that part which deals with pathology is likely to prove rather difficult of appreciation to the average student. It is strong meat, and in somewhat tough condition. One paragraph is positively misleading: "Drainage—the key to the problem of glaucoma—takes place through the cornea, which is freely permeable to water and dissolved substances, especially at the filtration angle." It is true that there follows on the next page a saving clause: "The drainage is not direct, but the aqueous must pass through the endothelium lining the anterior chamber, and is therefore directly proportional to the intraocular pressure." Nevertheless, we fear the first phrase is likely to lead the student to think that the cornea sweats aqueous like a porous pot its fluid contents. The book is well printed, on good paper, and it is well bound. There

* *Histopathology of the Teeth and their Surrounding Structures*. By Professor R. Kronfeld, M.D. Philadelphia: Lea and Febiger, 1933. (Pp. xii + 479; 385 engravings. 7 dollars net.)

* *Mayou's Diseases of the Eye*. By F. Ridley, B.Sc., F.R.C.S., and A. Sorsby, M.D., F.R.C.S. Fourth edition. London: H. Milford, Oxford University Press, 1933. (Pp. 250; 38 figures, 6s. net.)

are thirty-eight illustrations—no very liberal allowance for a student's book.

Companion with this is a *Student's Guide to Fundus Appearances*.⁶ This is an atlas of a dozen drawings of fundus conditions. There are sixteen pages of text describing the pictures. These pictures are printed upon a strip of stiff paper, which can be spread out so as to display the whole set side by side, with the descriptions to the left hand—a most convenient arrangement. The selection of drawings is good and the reproduction excellent. Picture No. 9 is composite, the upper half showing primary optic atrophy, the lower secondary atrophy. This close comparison would be good were the separation sufficiently marked; and it appears a mistake to have illustrated primary optic atrophy in an albino fundus. If the contrasted atrophy had been shown in fundi of average colour the lessons drawn in the text would have been more readily grasped. The atlas serves as a useful companion to the handbook.

Notes on Books

The third edition of Dr. AITCHISON ROBERTSON'S *Aids to Public Health*⁷ is designed to keep abreast of recent progress in the subject. Though the work contains much information compressed into small compass, the scope of the knowledge which it conveys is not up to the requirements of the student of medicine or of candidates for the diploma in public health. The book, however, is one of the best of its class. It may be cordially recommended to social workers, school teachers, and all other lay persons interested or practically concerned in hygiene or its applications.

A very good book of its kind is *Plants and Human Economics*,⁸ by RONALD GOOD, head of the department of botany in University College, Hull. It is full of important matter, reliable, comprehensive, well arranged, and written in an agreeable style. Its purpose is educational, not medical. It is an attempt to direct the teaching of botany to that aspect of the subject which has been largely neglected—its application to human affairs and activities. The facts bearing upon agriculture, forestry, industry—coal, petroleum, rubber, balsams, dyes, fibres—are mainly stressed; but indirectly the chapters on the nature and sources of food, and on alcohol and drugs, may be found of interest and value in relation to some aspects of medical science and practice.

The first issue of the new German annual entitled *Post-Graduate Clinical Medicine*,⁹ edited by Professor GEORG KLEMPERER, contains the following articles by leading German writers: diseases of the blood, by Professor Paul Morawitz and Dr. Heinrich Brugsch of Leipzig; vitamins, by Professor W. Stepp and Dr. J. Kühnau of Breslau; pellagra, by Professor Stepp and Dr. K. Voit of Breslau; vegetable diet, by Dr. M. Bircher-Benner of Zürich; treatment of diabetes in children, by Professor K. Stötte of Breslau; special forms of angina (agranulocytic, lymphocytic, and Vincent's angina), by Professor Werner Schultze of Berlin; progress in treatment by artificial pneumothorax, by Professor W. Unverricht of Berlin; sequels of persistent vomiting, by Professor H. Strauss of Berlin; pink disease, by Professor Erwin Schiff of Berlin; internal treatment of syphilis with spirocid and similar arsenical compounds, by Dr. Alfred Joseph of Berlin; vascular diseases, by Professor Morawitz

and Dr. Brugsch; disorders of glycogen storage, by Professor H. Beumer; undulant fever in man, by Professor C. Hegler of Hamburg; tularaemia, by Professor C. Sonnenschein of Hamburg; eugenics, with special reference to sterilization, by Dr. A. Fischer of Karlsruhe; puberty and its diseases, by Dr. E. Haase of Berlin; clinical use of electric ultra-short waves, by Dr. E. Schliephake of Giessen; acute pulmonary oedema, by Professor Leo Hess of Vienna; erysiploid, by Professor C. Sonnenschein; the problem of sleep, by Dr. H. Regelsberger of Erlangen; the effect of surgical and conservative treatment on senile manifestations, by Dr. Robert Lichtenstern of Vienna; the parathyroids, by Professor Georg Peritz of Berlin; metabolism and nutrition in tuberculosis, by Dr. Georg Schröder of Schomberg; cardiac and vascular hormones, by Dr. Karl Posener of Berlin; malaria therapy of tabes, by Dr. Paul Uhlenbruck of Cologne; diuresis, by Professor W. Nonnenbruch of Prague; and the pathology and treatment of detachment of the retina, by Professor G. Abelsdorff of Berlin.

FINDLAY'S *Physical Chemistry*¹⁰ is prepared with a view to securing for the student a broad foundation in the subject, so that it may serve either as an introduction to the general study or for the further pursuit of a more specialized section of it in any desired direction. It offers no short cut to the vocational training of any particular class of student, and is therefore perhaps the best kind of book for every beginner. It is exceedingly well written—so well as to be almost sufficient for instruction without the aid of lectures, which are usually regarded as indispensable. The subject is treated with special attention to the historical development of modern theories, a method which adds much to the interest as well as to the educational value of the work.

A second edition has been published of Professor MAX LEVINE'S introduction to *Laboratory Technique in Bacteriology*.¹¹ It consists of a series of more than a hundred short exercises designed for students commencing the study of bacteriology, and is intended to be, and is, a handbook for practical work. Instruction is given in the public health and agricultural aspects of bacteriological work as well as in the medical aspect. No doubt the book is much appreciated by Dr. Levine's pupils. Teachers also on both sides of the Atlantic might get some fresh ideas for "brighter bacteriology" by working through the table of contents.

¹⁰ *Introduction to Physical Chemistry*. By Professor Alexander Findlay. London: Longmans, Green and Co. 1933. (Pp. 492; 124 figures, 7s. 6d.)

¹¹ *Laboratory Technique in Bacteriology*. By Max Levine, Ph.D. Revised edition. London: Macmillan and Co., Ltd. 1933. (Pp. 289. 8s.)

Preparations and Appliances

LONDON HOSPITAL CATGUT

The special catgut prepared by the London Hospital Ligature Department (Whitechapel Road, E.) is the subject of an excellently produced and illustrated pamphlet and price list, which details the methods of manufacture from the pasture where the lambs are fed to the final sterilization of the finished gut. The antiseptic preparation begins immediately the animal is killed and the intestines removed. The intestines are thoroughly cleansed and frozen before dispatch to the ligature laboratories, where, after thawing, they are split longitudinally into ribbons, fat, muscle, and mucous coats are removed under spray, the ribbons being then immersed in alkali baths, measured into lengths, and fixed to loops for antiseptic treatment before spinning into ligatures while saturated with an inhibiting agent. The illustrations in the pamphlet show that throughout the work the most hygienic conditions obtain, and every stage of the process is checked by many bacteriological tests. The utmost degree of sterility, a capacity for absorption in the muscle within approximately the times specified on the label, and highly satisfactory properties as regards tensile strength and elasticity are claimed for this product. Particulars are also given of Souttar eyeless needles, with which London Hospital catgut may be used.

NITROUS OXIDE: HISTORY AND DEVELOPMENT*

BY

H. EDMUND G. BOYLE, O.B.E., M.R.C.S.,
I.R.C.P.

SENIOR ANAESTHETIST TO ST. BARTHOLOMEW'S HOSPITAL

The discovery of nitrous oxide by Joseph Priestley in 1776 may justly be described as the dawn of anaesthesia. In 1798 the Pneumatic Institute was founded by Dr. Beddoes at Clifton; Bristol, for the treatment of phthisis and other lung conditions by inhalation of gases. Humphry Davy was an assistant at the Institute, and in 1800 he published a book on nitrous oxide, in which this passage occurs:

"As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations where too great an effusion of blood does not take place."

Here we have the first clear and definite mention of the use of nitrous oxide as a general anaesthetic, but it was not until nearly half a century later that this suggestion was actually put into practice. This brings us to one of the saddest periods in anaesthetic history, for by ignoring the work of one of its greatest sons this country lost the proud distinction of giving general anaesthesia to the world a quarter of a century before Wells and Morton. I refer to Henry Hill Hickman, who was born in 1800, the very year in which Davy made his observation. At the age of 20 he obtained the M.R.C.S., and practised at Ludlow in Shropshire. Impressed by the sufferings of those upon whom he was called to operate, he resolved to seek some method of alleviating their pain by rendering them unconscious before operation. He experimented on animals by asphyxia, nitrous oxide, and carbon dioxide. He then operated on animals, and met with considerable success. He decided that if his methods were applied to the human subject they would become of the greatest value to mankind in making painless the performance of major surgical operations. The profession in England derided this work, and condemned it as dangerous and useless. Disheartened, he resolved to lay the matter before the Royal Academy of Medicine in Paris; little was done, only Larry (Napoleon's surgeon) showing any belief in the work. The young surgeon, disappointed and hopeless, returned to England to die at the early age of 29. In 1930 a deputation from the Anaesthetic Section of the Royal Society of Medicine, mainly at the instigation of Dr. Hughes, visited Ludlow, and attended a religious service and the unveiling of a tablet to commemorate this early pioneer's work.

The discovery of ether about 1830 rather ousted nitrous oxide, and it was not until 1844 that H. Q. Colton, who is described by a writer as an itinerant lecturer, gave an entertainment at Hartford, Connecticut, where people in the audience inhaled nitrous oxide for its exhilarating effect. Horace Wells, a dentist of that city, who was present, noticed the freedom from pain that attended the accidental injury of one of the subjects. He was greatly impressed, and persuaded Dr. Colton to give him gas on the following day, while Dr. John M. Riggs, another dentist, was invited to extract a tooth. The experiment was a complete success, and on recovering Wells declared that he had had no pain whatever. He then, in conjunction with Riggs, began to use the gas freely in his practice. Later on he gave a demonstration at Massachusetts General Hospital, but the facepiece was removed too soon, and the patient gave a yell, whereupon Wells was hissed out of the theatre as an impostor. This is quite easy to understand when one reflects that the method of administration at that time was to fill a bladder with the gas, which was inhaled by means of a pipe through the mouth, while someone held the nose. Wells died in 1848, having severed a vessel in his arm and taken ether to render death painless.

Bigelow states that in 1848 a patient had her breast removed under nitrous oxide gas, which was given through a valve mouthpiece and a flexible tube leading through a

bladder to two large copper reservoirs filled with gas. He states:

"After several inspirations the patient's lips and the most vascular part of the tumour began to assume a purple colour. She remained quiet, however, and in a short time was evidently insensible."

In 1875 Dr. C. A. Brackett kept a patient under nitrous oxide for about thirty minutes while Dr. Squier removed a cancer of the breast. Dr. Brackett describes it as a "grand success." The patient was not conscious of the operation, and he adds, "I believe this is the first achievement of the kind in New England." (He obviously was not aware of Bigelow's experiment in 1848.)

MANUFACTURE AND CONTAINERS

During all this time nitrous oxide had to be prepared just before the operation, and was kept in a sort of gasometer, but I have obtained a short description of what happened in those days from Mr. H. S. Coxeter, a great-grandson of the original Coxeter. He says:

For some of the earliest cases of nitrous oxide anaesthesia, both in the laboratory and in private dental practice, the gas was supplied in ox bladders, the patient inhaling the gas through the outlet tap, while his nose was pinched by one assistant and the bladder was squeezed by another. It is true that these early cases were mostly of an experimental nature, although slight operations were often performed under a sufficiently deep, but sometimes unexpectedly short anaesthesia. These bladders of nitrous oxide were regularly supplied by J. Coxeter and Son for use at the old University College Hospital opposite their premises. The gas was made by heating ammonium nitrate in glass laboratory retorts over a Bunsen burner and collecting it under water, no further washing being then considered necessary. The interest taken by the surgeons in the new anaesthesia, and its immense popularity among the students, due largely to the amusement caused by the hilarious excitement exhibited by the patient under this crude method of administration, pointed to a great future for "laughing gas."

Delivery by messengers carrying bundles of bladders like a toy balloon seller was obviously impracticable, and Mr. Coxeter quickly had some cylinders made of wrought iron tubes with welded tops, bottoms, and seams. Into these the gas was pumped by hand, with a great expenditure of time and energy, and the gas sold according to the varying amount it had been reasonably possible to pump in. As the demand increased it became obvious that a more rapid method of manufacture and filling was necessary, and a factory was started in a covered yard, in which a gas-engine-driven compressor was installed. The heating of the ammonium nitrate was now done in cast iron retorts, into which melted ammonium nitrate was poured through a funnel and the orifice plugged securely. The retort was then heated over a gas ring, and the nitrous oxide bubbled through into Woulfe's bottles containing a solution of caustic potash, entering a small gasometer, from which it was pumped into the cylinders.

For a time there was a state of considerable tension in the workshop, as no one quite knew what might or might not happen either during the manufacture of the gas or the filling of the cylinders; the latter, although extremely heavy, had a nasty habit of developing a sudden and alarming leak at one of the seams. Also the ammonium nitrate, not having the high degree of purity obtained later, was somewhat erratic in its behaviour, and upon the appearance of white fumes in the Woulfe's bottles, hose pipes were turned on to the retort with all speed. Sometimes even this was ineffective, and as the gas came off with ever-increasing force and fury, it was left in sole possession of the workshop, and the workmen anxiously awaited events outside. Improved methods of manufacture have been in use for some years, and the gas is now delivered in a very pure state. The unsatisfactory iron bottles were replaced by drawn steel seamless cylinders. Cast brass valves were replaced by those of a tougher alloy, stamped or drop-forged.

The steel cylinders were very heavy, and after the war I endeavoured to get permission to use some cylinders, made, I believe, of aluminium, which had been used by the Air Force to carry oxygen, and were very light. There were several objections, the chief being third-party risks (injury to the workmen when filling them), and we were

*A paper read before the North Staffordshire Medical Society.

not allowed to use them. Now, however, new steel has been evolved known as vibrac steel. This is a nickel, chromium, molybdenum, and manganese alloy; it is light and strong, and apparently conforms to all the tests that are required by the Government.

GAS AND OXYGEN IN PROLONGED ANAESTHESIA

Colton revived nitrous oxide in 1863, and in 1867 was able to give a record of 20,000 cases. In 1868 a demonstration was given at the Dental Hospital in London by Dr. Evans, a dentist from Paris, and after this the use of the gas spread enormously. In 1868 Andrews published accounts of a number of cases in which he had obtained a non-asphyxial form of anaesthetic by using oxygen with nitrous oxide.

In a little manual on nitrous oxide, or "laughing gas," by F. R. Thomas, published in 1870, we find some diverting reading. Among other things we are reminded that Faraday liquefied gas in 1822. The manufacture of nitrous oxide before the operation is described in very great detail. The author says that in purifying the gas it is unnecessary to use anything but a solution of the sulphate of iron in one bottle and fresh water in the other two. Some chemists recommend the use of caustic potash in addition, for the purpose of neutralizing any chlorine gas that may be present.

"In my judgement, however," says F. R. Thomas, "the use of these chemicals is superfluous, as I have found by experience that the action of the gas is precisely the same, whether it is washed through those solutions or whether it is washed through fresh water and allowed to stand a sufficient length of time (about 5 or 6 hours) for the water in the gasometer to absorb any impurities that may have passed over with the gas."

How different that is from present-day conditions, when the gas is most carefully washed and presented to anaesthetists free of water and, as is described by the suppliers, as non-freezing gas! In another place Thomas says:

"I am therefore confirmed in the opinion that after nitrous oxide has been kept over four or five days it becomes very much deteriorated by the absorption and loss of oxygen."

It would appear, therefore, that this Dr. Thomas had very definite ideas on the subject of nitrous oxide, and it is interesting to see how in the course of time the opinions that he then expressed have been considerably altered.

Clover and Coleman first gave continuous nitrous oxide through the nose, but it was not used for prolonged cases until somewhere about 1895, when Herbert Paterson began giving nitrous oxide through the nose for prolonged dental cases. Bellamy Gardiner, working quite independently of Paterson, produced papers shortly afterwards showing that nitrous oxide and oxygen could be given for lengthy periods. Paterson used to go round the country giving demonstrations of prolonged nasal gas for dental work, and he has himself told me that on several occasions he gave these dental gases for well over an hour. Paterson soon took up surgery, and the administration of prolonged gas and oxygen was carried on mainly by Bellamy Gardiner. Just previously Sir Frederick Hewitt had produced his gas and oxygen machine, and it was with this machine, or an adaptation thereof, that Bellamy Gardiner worked. Hewitt's machine did not permit of rebreathing, and so it missed one of the essential points of gas-oxygen anaesthesia. Later on Harvey Hilliard introduced a method of passing a catheter through the nose into the post-nasal space, through which he delivered gas, and obtained a prolonged anaesthesia for dental work.

Up to this time gas and oxygen had not been used extensively in this country, and it was the advent of Teter and Gwathmey to an international conference in 1912 that gave a much-needed impetus to and interest in the method. Teter gave a demonstration at Guy's in 1912, and after that Chaldicott and Page tried to popularize gas and oxygen, but interest in the anaesthetic was very lukewarm. Soon after the beginning of the war I obtained from Dr. Gwathmey one of his machines, and began to use the method. In October, 1917, I read a paper before the Medical Society of London on "Experiences of the Use of Nitrous Oxide and Oxygen with

Rebreathing in Military Surgery." It is interesting in the light of subsequent development to read the criticisms that were levelled at it, but that is past history, and nowadays most anaesthetists give gas-oxygen-ether.

It may be of interest to note here that very soon after the publication of this paper the War Office demanded several machines—machines which were being made by Coxeters and sold as Boyle's gas-oxygen-ether apparatus. Coxeters were unable to supply these needs, most of their staff having been called up, and so the War Office had the machines made by Siebe Gorman and Co., and I well remember being sent there to pass them as fit for use at the front. Machines as made then were very crude compared with the finished article to-day, but on some occasions I had to pass as many as three dozen.

The main points which came out during the discussion of my paper before the Medical Society of London were:

(a) that there was hardly any rise of temperature after an operation under gas-oxygen with a little ether, as compared with ether or chloroform alone. Moreover, as the patients were conscious very soon after the operation had finished, it was obvious that the work of the nursing staff was greatly lessened; (b) that severely wounded and septic men did much better under gas and oxygen than under ether or chloroform.

After the war the development of gas-oxygen-ether for civil practice became essential. The endotracheal administration of ether had been in vogue since 1912, and it now appeared that we thought it advisable to try the endotracheal administration of gas-oxygen-ether. This met with great success, and to-day the endotracheal administration of gas-oxygen-ether is my routine for abdominal operations. My reason for this is that a very quiet abdominal wall is obtained, and indeed in a good gas the relaxation of the abdominal wall is almost, if not quite, equal to that obtained by a spinal anaesthetic.

Many alterations and improvements have been made in the endotracheal method. The most important is perhaps the one advised by Dr. Magill, who passes a soft rubber tube, about the size of one's finger, down the nose and into the trachea. Then, if necessary, he can pack the fauces, and so prevent any blood from being inhaled. When this tube is in position gas and oxygen alone will suffice for most operations. There have, of course, been other alterations, but this is probably the most important. Another method, and one which is required by some throat surgeons, is to introduce two catheters into the trachea, the idea being that if the fauces are then packed the anaesthetic can be given by one tube while the other tube takes off the expired air.

No paper on nitrous oxide would be complete without the mention of E. I. McKesson of Toledo, Ohio, who has produced more apparatus and has probably done more work on nitrous oxide than almost anyone in the United States of America. McKesson, on occasions, practises what he calls "secondary saturation" with gas to produce relaxation. When I saw him do this it was an alarming sight. It consisted of giving gas until the pupils were widely dilated, the colour was grey, and the patient looked like death. Then the lungs were distended with oxygen, and gradually the colour returned to pink. "That is primary saturation," said McKesson, and then he proceeded to do it all over again—a method I am glad to have seen, but not one that I am prepared to teach to students. McKesson is a very able anaesthetist, and has certainly produced a most excellent machine.

The next development in gas-oxygen-ether anaesthesia was its use in midwifery. In 1921, when I was in America as the representative of the Royal Society of Medicine, I found that they were giving gas-oxygen for childbirth. On my return to this country I endeavoured to follow their example, but for some time obstetricians were rather shy of it. At last one of them took the plunge, and since then he and others have been using it. The method is to administer gas with each pain, and, briefly, only to use ether at the end of labour, just before the child is born. The addition of a little carbon dioxide used with discretion and care enables one, to some extent, to shorten the labour, to produce the child a rosy pink, and, I think, to shorten the time for the delivery of the

afterbirth. This method is useful in hospitals, but it is not suitable in general practice in outlying districts of the country. Should the time ever come when all the women of this country are confined in institutions, it will then become possible to use this method on a large scale. At the moment, however, although we are supplied with comparatively light cylinders, the method is impracticable for country districts because there must be one person to give the anaesthetic and another to deliver the child.

In the new surgical block at St. Bartholomew's Hospital there has been installed, at my suggestion, an equipment by which gas-oxygen and carbon dioxide is stored in the basement, and is then taken by a series of pipes to the five anaesthetizing rooms and to the five theatres; it is thus perfectly easy to give gas-oxygen or carbon dioxide by simply turning a tap, and we have no cumbersome cylinders about the theatre.

In conclusion, I should like to thank my friend Dr. Eric Worsley Gandy for the loan of the valuable collection of books on the early days of nitrous oxide, and also Mr. H. J. Bennett of Coxeter & Son for his very interesting information.

FORMATION OF A VOLUNTARY HOSPITALS' COUNCIL FOR LEEDS

For a good many years negotiations have been carried on between the Boards of the General Infirmary at Leeds, the Hospital for Women at Leeds, and the Leeds Maternity Hospital, with a view to promoting co-operation between the three institutions. As a result of these a Voluntary Hospitals' Council has been formed, some details of which are given below.

First, however, something must be said concerning the separate development of the three hospitals, and the scope of their work at the date when the newly constituted council became operative on January 1st of this year. Those who are responsible for the administration of the medical charities of Leeds, and certainly those who are concerned in medical education and in research, have always regarded it as a fortunate thing that, apart from certain special departments, most of the work has been concentrated in that institution the correct name of which is the "General Infirmary at Leeds," not the "Leeds General Infirmary," and this is indeed right when one considers the large area from which the hospital draws its patients. Founded in the year 1767 by the first William Hey, it carried on its work in a succession of centres until the present building—one of the first in the country to be erected on the pavilion system—was opened in the year 1868. In 1894, under the chairmanship of Mr. Benson Jowitt, the building was considerably enlarged, and after the war the extensive additions and alterations, which arose from the inspiration of Mr. Charles Lupton, were completed. Many years ago there used to be an eye institution in Leeds, but this was taken over by the Infirmary, with some necessary adjustment of the staff. For some time the dual posts of ophthalmic and aural surgeon were held by the same honorary officers, of whom there were two. These departments, however, were separated about twenty-three years ago, and there are now two ophthalmic surgeons and two surgeons in charge of the ear, nose, and throat department.

Until 1885 students of medicine in Leeds were dependent on their association with private practitioners for experience in midwifery. At this time a new honorary post was instituted, and the gynaecological and obstetric department came into existence. A certain number of beds was allotted to the gynaecological work, and this also had an out-patient department, which rapidly increased in size. The work of organizing the new external maternity department was most ably carried out by the newly appointed resident obstetric officer, the late Dr. O. Croft, to whose work the School of Medicine owes a great debt. There was no accommodation for in-patient obstetric work; it was very exceptional for a woman to be delivered within the walls of the Infirmary. The relation of the Infirmary to the Hospital for Women and Children deserves notice. The latter institution had been in existence for many years, and was not associated with

the School of Medicine. Under the chairmanship of the late Mr. Fred. Spark a new hospital was erected, and some beds were set aside for the delivery of women who required hospital treatment. The accommodation in the General Infirmary for children, and especially for those suffering from medical as contrasted with surgical ailments, had been ridiculously inadequate for many years. The writer of these paragraphs recalls that the sole accommodation for this class of patient in 1883 constituted three cots in the female medical ward. By an arrangement with the Hospital for Women and Children it was agreed that its title should be changed to the Hospital for Women, that it should cease to admit children, and that it should undertake both the external and the limited in-patient maternity work, while the increase in the available beds at the Infirmary would make it possible greatly to extend the accommodation for medical children. The Leeds Maternity Hospital has had a wonderful development, both in respect of rapidity and efficiency, and some time ago it was deemed right that it should take over all the work in connexion with the external and internal maternity departments. The University interested itself in the matter, and now students have considerable facilities for gaining experience in maternity work.

These details have been given to make clear the state of affairs which has happily developed in Leeds, and which has made it possible, without friction, to arrange for intimate co-operation between, and for a partial fusion of, these three institutions, while leaving to each a large degree of autonomy. There came into operation on January 1st of this year the Leeds Voluntary Hospitals' Council. This is composed of six representatives of the Board of the General Infirmary, and three each of the Hospital for Women and of the Maternity Hospital, and it also includes every member of the honorary staff of the three institutions, together with the warden of the dental department and two other representatives of the honorary dental staff. Thus there is perpetuated the happy state of affairs which has always prevailed at Leeds: that the honorary staffs are fully represented on the Boards of all the institutions, though with some restriction as to voting powers. The duties of the council will be concerned with questions of policy, such as those dealing with extraordinary capital expenditure, alterations in the relative proportion or character of the work to be undertaken by the three component institutions, and generally any questions which may be referred to it by any of the three Boards concerned. At present it is arranged that all the gynaecological work shall be done at the Hospital for Women, all the maternity work at the Maternity Hospital, and everything else at the General Infirmary. The honorary staffs of the three hospitals are combined to form one "Faculty." The honorary staff of the Infirmary has always had this title, and it is one which is jealously held. When it was suggested a good many years ago that the term should be limited to the Faculty of Medicine of the University this was not agreed to. The "Faculty of the Infirmary" was sacrosanct! Among other duties this joint Faculty will have the election of all the members of the resident staff in its hands, and in the future a great many matters will be referred to it by the three Boards concerned.

Perhaps one of the most important considerations in connexion with the formation of the council is the method of election of the members of the honorary staffs. This is to be in the hands of the lay representatives of the council—twelve in number, it will be remembered—together with six others who are not members of the Boards of any of the hospitals, and one-third of whom shall retire annually, and two medical members appointed annually by the council of the University of Leeds. Uniformity as to the qualifications necessary for all candidates for honorary posts has also been secured, and the conditions which have for long prevailed at the Infirmary will apply in future to all the three hospitals. These are that assistant physicians and physicians must be graduates in medicine of a university of the United Kingdom and Members or Fellows of the Royal College of Physicians of London; and that all assistant surgeons and surgeons must be Fellows of the Royal College of Surgeons of England.

It is confidently expected that this scheme of co-ordination will be attended with increased efficiency in the working of the three hospitals, and will enhance the reputation of Leeds as a teaching centre.

British Medical Journal

SATURDAY, JANUARY 27th, 1934

STERILIZATION

In June, 1932, the Board of Control, following a deputation to the Minister of Health from the County Councils Association, the Association of Municipal Corporations, and the Mental Hospitals Association, and with the approval of the Minister, appointed a Departmental Committee on Sterilization. The "sterilization of the unfit" has been for so long before the public in the shape of letters to the Press from high, though not always instructed, authorities, memorials from public bodies, and even grave warnings from the Bench, and is at once so vital and so controversial a topic, that the report of the committee has been awaited with intense interest not untinged with anxiety. The report, an account of which in some detail will be found in another column, was presented to Parliament on January 18th. The committee of eight members, appropriately presided over by Mr. L. G. Brock, chairman of the Board of Control, sat on thirty-six occasions and took evidence from sixty witnesses, whose names are given in an appendix to the report. The terms of reference, set out in full in our descriptive article, were so wide, embracing questions medical, biological, economic, and social, that the witnesses were necessarily chosen from many fields of work and authoritatively represented separate though complementary interests and different disciplines.

The committee's first task, admittedly impossible within the limits of its report, was "to examine and report on the information already available regarding the hereditary transmission and other causes of mental disorder and deficiency." Deciding, therefore, to confine its inquiry to those aspects of causation which had the most direct bearing on the question of sterilization, it considered the evidence as to the relative importance of "heredity" and "environment." On this point, which is a problem in eugenics that lies at the root of the whole matter, the committee has to admit that the witnesses who gave evidence were not in agreement as to the mode of transmission of mental defect and disorder, though all recognized heredity as an important factor in the causation of these conditions. The biologists, in fact, were at variance; and, as the committee rightly says, "much research will be necessary before a conclusive decision can be reached, and it may be possible that in the light of future knowledge prevention will in some cases be effected by a modification of the environment." Turning away, however, from conflicting theories about the mode of transmission—the solution of which, it may be maintained, can alone prove beyond question the place and importance of heredity in the causation of mental disorders and defects—the committee, keeping in mind the practical

aim of its deliberations, states the argument for the acceptance of heredity as an important factor of causation as follows: "A substantial, if not indeed a high, proportion of patients in mental hospitals and institutions for the mentally defective have one, two, or more relatives who also have suffered from some form of mental disease or defect. If the incidence of mental abnormalities in these families prevailed in all other families of the general community the numbers of mental patients would be considerably larger than the most reliable statistics indicate." This is the "familial concentration" on which most psychiatrists are said to base their belief that mental disorder and defect are to a great extent inherited conditions, or, as Lord Horder said a short time ago, "Like tends to breed like."

Before passing from this part of the report an investigation to which the committee attaches considerable importance should be mentioned. It is an inquiry, clinical and psychological, still incomplete, by Drs. L. S. Penrose and Douglas Turner at the Royal Eastern Counties' Institution for Defectives at Colchester. Among the first 513 patients examined the proportion of cases in which the amentia was thought to be due entirely to hereditary causes was 29 per cent., and the proportion of cases entirely due to environmental conditions was put at 9 per cent. The committee says that it is necessary to regard the remaining 62 per cent. as suffering from mental deficiency conditioned by both heredity and environment; for, however logically convenient the antithesis between heredity and environment may be, there are genetic characters which will produce a given character whatever the environment, and others which only produce a given character in an environment favourable to its production. Thus hereditary factors were found, or inferred, in 91 per cent. and environmental factors in 71 per cent. The committee refers to "abnormal conditions of the pregnant mother, hitherto unrecognized, which may interfere with development to such an extent as to cause mental defect." Doubtless in saying this the committee had in mind the intensive research, itself in its infancy, now being conducted into the physiology of reproduction and the effects of internal gland secretions upon the development of the embryo, with, as a corollary to the growth of this science, an augmentation of the role of environmental and possibly remediable factors.

The committee was asked "to consider the value of sterilization as a preventive measure, having regard to its physical, psychological, and social effects, and to the experience of legislation in other countries permitting it." In dealing with the social effects it takes occasion to deplore the fact that many advocates of sterilization in the past have supported this in the belief that it will serve as a substitute for the provision of institutional accommodation. This belief, it says, is illusory. Sterilization "does nothing to improve the mental condition and it does not lessen sexual activity. The unstable and antisocial defective remains unstable and antisocial. The thief remains a thief. The erotic girl or youth will still need institutional

care. The impossibility of procreation will not save them from being a social menace." Nor, it points out, will sterilization reduce to any appreciable extent the present wide disparity between the number of institutional beds available and the estimated number of beds needed. Actually the proportion of patients now in institutions who if sterilized could be released to the outer world is exiguous.

The case for sterilization of the subjects of mental disorder and defect, as a social measure, hinges virtually on two points: (1) the fact that approximately two-thirds of all defectives are capable of community life; and (2) that defectives make inefficient parents. It is true that owing to shortage of accommodation the proportion of all defectives living in the community is nearer to five-sixths; and it may be true that here and there there are defectives, able to run a household with a fair measure of success and wishful to marry, who, if sterilized, could do so without ill effect. As against this there is the risk of increased sexual promiscuity, which the committee, though it has failed to find any evidence of this after painstaking inquiry, does not dismiss as imaginary. It would be in the highest degree unwise, it declares, to assume that sterilization will in any way lessen, still less obviate, the need for supervision and after-care. Before coming to a conclusion as to the justification for sterilization the committee considered first the question of compulsion. Interpreting its reference as asking it whether there was on scientific grounds an unassailable case for compulsory sterilization it came to the conclusion that in the present state of knowledge the case for compulsory sterilization could not be established. There were other arguments against compulsion, but the sufficient reason clearly was that the committee assumed "the legislature would not feel justified in compelling any persons to submit to sterilization unless it could be shown beyond reasonable doubt that some at least of their offspring would either be mentally defective or would develop mental disorder," and of this no proof could be produced. With regard to voluntary sterilization the committee did not entertain the same doubts, and unanimously recommended that voluntary sterilization be sanctioned, on the grounds that enough is known "to be sure that inheritance plays an important part in the causation of mental defects and disorders . . . and that mentally defective and mentally disordered parents are, as a class, unable to discharge their social and economic liabilities or create an environment favourable to the upbringing of children," with the rider that there is reason to believe that the opportunity for sterilization would be welcomed in some cases by the patients themselves.

The committee argues forcibly that the case for legalizing sterilization rests upon the broad principle that no person, unless conscience bids, ought to be forced to choose between the alternative of complete abstinence from sexual activity or of risking bringing into the world children whose disabilities will make them a burden to themselves and society. This necessarily introduces the subjects, or the "carriers," of grave physical disabilities shown to be transmissible,

and such persons are therefore included within the committee's recommendations. Unfortunately the "carriers" of mental disabilities, though estimated as ten times more numerous than the affected persons themselves, cannot be identified with the same certainty as can the "carriers" of, say, haemophilia or hereditary blindness, whose mode of transmission is known. "The carrier," says the committee, "is the crux of the problem." From the point of view of eugenics the carrier may prove the stumbling-block also. Though there are many other points deserving notice—and particularly the part to be played by medical men, on whose shoulders the real responsibility will fall should the committee's recommendations become translated into law—it would be ungracious to conclude without paying tribute to the report as a model of arrangement of subject-matter and treatment.

CONTINUITY IN THE CURRICULUM

In recent years the unsatisfactory state of the medical curriculum has been a topical subject of wide popularity both in the medical and in the lay press. There is universal agreement on certain points. No one denies that the curriculum is overcrowded; everyone agrees that the knowledge retained by the student at the end of his course appears to be a meagre result after five or six years of intensive and expensive training for a special purpose; and the teachers in every year of the course complain that students, before coming under their care, have learnt a vast amount of detail but have failed to acquire any real grasp of essential principles. The natural consequence of this latter belief is to concentrate criticism upon the first years of the medical curriculum, for the teachers of these preliminary subjects are in the unfortunate position of having no one to whom they can readily pass back the criticisms levelled at themselves. The practical value of the agreement existing in regard to these general principles is lessened, however, by the fact that agreement automatically comes to an end as soon as the details of reform are considered.

Many competent critics are of the opinion that the most difficult problem in any reform of the medical curriculum is the transition from laboratory to clinical teaching. At its worst this transition may result in a very large part of the training in anatomy and physiology being wasted. The student acquires a systematic knowledge of these subjects, passes an examination, then forgets nearly all the knowledge he has gained, and later re-learns certain details of immediate clinical importance without attempting to correlate these with any general principles. This disharmony is probably at its worst in the relation between physiology and clinical medicine, and there is a general agreement that every effort ought to be made to achieve more continuity in the teaching of these subjects. One of the simplest methods of attaining this is for the students in their later years to receive instruction in the application of physiological principles to clinical problems,

but there is considerable difficulty in finding teachers who have an adequate knowledge both of the science of physiology and of the practice of clinical medicine.

An interesting attempt along these lines has been made at Strasbourg. This enterprising school of medicine is fortunate in the possession of a number of distinguished workers in the province that may be termed either "experimental medicine" or "functional pathology," and a group of these have collaborated to provide a course of lectures.¹ The scope of the lectures and the extent of the collaboration attained is best indicated by mentioning a few of their titles: renal physiology, by L. Ambard (clinical medicine); mineral metabolism, by Schaeffer (physiology); cerebral localization, by C. Pfersdorff (psychiatry); physiology of capillaries, by A. Schwartz (pharmacology). The lectures give a clear and accurate account of modern knowledge in the important fields they cover, while the collaboration of workers in a wide range of subjects provides a stimulating variety of outlook. A similar series of lectures in medical pathology was published in 1931 and a second series in that subject is also appearing. The courses are intended for final-year students and graduates. This method of instruction that is being worked out on practical lines at Strasbourg seems to us a very interesting and promising attempt to strengthen one of the weakest links in a medical education. In its interim report published last summer² the special committee set up by the British Medical Association laid stress upon the need for a "co-ordinated course of study," and every means to that end is worthy of notice.

METHYLENE-BLUE AS AN ANTIDOTE

Methylene-blue has long been used by biochemists on account of its power to promote the oxygen uptake of isolated tissues, and in 1926 Sahlin³ showed that it could act as an antidote to cyanide poisoning in laboratory animals. These experimental results were confirmed by Eddy⁴ and Brooks,⁵ while Geiger⁶ successfully applied the drug in the treatment of patients suffering from cyanide poisoning. He treated the cases by injecting intravenously 100 c.cm. of 1 per cent. solution of methylene-blue. Hug⁷ concluded that the good effect was attributable to the action of methylene-blue in transforming haemoglobin to methaemoglobin, because the latter substance forms a very stable compound with cyanide, and for this reason he investigated the use of sodium nitrite as an antidote to cyanide poisoning and found it more effective than methylene-blue. Wendel⁸ obtained similar results. Hug also carried out research into the action of other drugs which form methaemoglobin, such as pyrogallol

and sodium thiosulphate. Some of these experimental results have been confirmed by other workers. Chen, Rose, and Clowes⁹ measured the number of minimum lethal doses of NaCN that could be detoxified in dogs by various antidotes, and obtained the following results: methylene-blue, 2; $\text{Na}_2\text{S}_2\text{O}_3$, 3; NaNO_2 , 4; NaNO_3 and $\text{Na}_2\text{S}_2\text{O}_3$, 13. A combination of nitrite and thio-sulphate is therefore about six times as potent an antidote to cyanide poisoning as is methylene-blue, and doubtless this advance will before long be applied in therapeutics. These findings are of considerable practical value, but their theoretical basis seems somewhat uncertain, since Haggard and Greenberg¹⁰ observed that large doses of the dye transformed only about 10 per cent. of dog's haemoglobin to methaemoglobin, and Geiger found no measurable quantity of methaemoglobin in a case of cyanide poisoning which he treated with methylene-blue. The theoretical aspect of the problem has been further complicated by the results of Geiger, who claimed that methylene-blue injections acted as an antidote to carbon monoxide poisoning. Nass¹¹ and Christopherson¹² also reported the successful treatment of cases of carbon monoxide poisoning with this dye. This is the commonest form of poisoning that occurs, and hence the claim is of great practical importance. Hanzlik¹³ pointed out that the result was incomprehensible on theoretical grounds, because the essential trouble in carbon monoxide poisoning is the inactivation of haemoglobin, and this was not affected by methylene-blue. Haggard and Greenberg reviewed the theoretical aspects of the problem, and showed experimentally that in dogs poisoned with carbon monoxide methylene-blue produced no benefit, but rather injury, in that it further reduced the oxygen-carrying power of the blood, by transforming some of the haemoglobin to methaemoglobin. A result obtained by Williams and Challis¹⁴ makes it even more difficult to understand the action of methylene-blue, for they successfully treated a case of aniline dye poisoning by injections of the dye, and found that the treatment brought about a rapid conversion of methaemoglobin to normal oxyhaemoglobin; they confirmed this observation by experiments on rabbits. The results reported from methylene-blue therapy appear, therefore, to be extremely contradictory. In some cases administration of the dye was accompanied by the formation of methaemoglobin, and in other cases it caused methaemoglobin to be removed. Furthermore, methylene-blue injections were attended by benefit both in cases in which the production of methaemoglobin might have been beneficial and in cases in which such a change would certainly have been deleterious. Haggard and Greenberg pointed out that injections of methylene-blue were associated with marked stimulation of the central nervous system. This effect has been described by previous authors (Heffter¹⁵). It would appear from the evidence that methylene-blue injections exert two actions: first, a stimulant effect on the central nervous system that is of transient value in a wide variety of cases of poisoning; and, secondly, some peripheral action that is of specific value in cyanide poisoning.

PROPHYLAXIS OF MEASLES

Tracing the history of active immunization against measles J. Comin¹ states that in 1758 Home of Edinburgh tried inoculation by scarifications into which blood and mucus from patients acutely ill of measles was rubbed. Cock carried out similar experiments with the lachrymal secretion. In 1801 Rasori of Parma used a needle, and in 1822 Speranza of Mantua a lancet, dipped in the blood of measles patients; the latter method was adopted by Mihaly in Hungary with success in 1,122 cases. In 1850 MacGillivray was severely criticized for attempting immunization by injection of blood taken from acute cases, and no further work on these lines was carried out until Hectoen, in 1905, employed blood from acute cases diluted with ascitic fluid. Stimulated by Hectoen's results, Kamoto tackled the problem of finding the dose of antigen devoid of danger which would produce immunization. He began by diluting the antigen with 10 per cent. of sodium nitrate. In 1926 Degkwitz injected diluted blood (1 in 6, or 1 in 8), which he set aside for two weeks, and then administered in doses of from 0.1 to 0.4 mg. Saoni employed a 0.5 per cent. solution of carbolized blood, but Debré was the first to use the serum of convalescents, which he gave in doses of 1 c.cm. of a 1 in 400 to 1 in 800 solution. Immediate leucopenia, followed later by a leucocytosis, was noted in these experiments of Debré. In 1927 Degkwitz, with a 7 per cent. dilution of blood from acute cases, produced in the monkey a catarrhal measles, devoid of exanthem, but immunizing the animal from a second attack. Treatment with the serum of convalescents had been also instituted by Weisbecker in 1896, Blumenthal in 1897, and Ribadeau Dumas in 1918, but became of great interest after the work of Nicolle in 1916 and Pacheco in 1920, in which year Degkwitz declared the minimal active dose to be 3 c.cm. if employed within three days of exposure to the infection. Comin advises that the blood should be taken from a healthy convalescent seven or eight days after the temperature has fallen to normal, and recommends, if obtainable, a mixture of the blood of three such donors, all of whom have been shown to be exempt from tuberculosis and syphilis. To this he adds 0.5 per cent. phenol, storing each unit in an ampoule and injecting up to and including the sixth day after exposure. Lereboullet states that the period of incubation in measles is from nine to eleven days, and is characterized by a subfebrile temperature, loss of weight, and polyneuclosis, which Pirquet ascribed to the development of antibodies. Teunier states that the daily loss of weight is 70 grams; while Combe avers that the polyneuclosis, which appears six days before the rash, is neutrophile, and with the rash changes to a mononucleosis in all uncomplicated cases. Comin gives a dose of 4 c.cm. to children under 4 years and of up to 8 c.cm. to a child over 5. After the seventh day following exposure he advises doses of from 15 to 20 c.cm. When this convalescent serum cannot be procured he suggests the trial of serum or blood of healthy adults who have had measles, in doses of from 25 to 50 c.cm. of serum, or of blood from 60 to 150 c.cm. Knefelmacher of Vienna reports great success following injection of blood from adults who have had measles and who have been made still

more immune by injections on three successive days of 10 c.cm. of blood from acute cases. Salazar de Souza of Lisbon had 78.7 per cent. of successes following the injection of healthy placental blood.

CONTROL OF INDOOR ATMOSPHERE

During the last few years much industrial research has been carried out on the control of air conditions indoors. It is not difficult to imagine the benefit to comfort, efficiency, and health of working and playing in an atmosphere neither too hot nor too cold, neither too dry nor too damp, from which all soot and dust and other impurities have been removed, and which is kept in steady circulation without draughts. Rooms would need less "dusting" and cleaning; pianos would keep their tune; furniture and hangings would last much longer. Properly air-conditioned restaurants and theatres are cool and fresh, with favourable effects on the appetite and interest respectively, and it scarcely needs proof that disease of the upper respiratory tract should be harder to transmit in an ideal atmosphere than in an unhealthy one. The field for air-conditioning in commerce and industry is almost infinitely varied. All food keeps better under ideal air conditions; cotton manufacture, brewing, and many other industries need special conditions of temperature and humidity; much photographic and other process work requires a controlled atmosphere. The innovation has not yet been tested in English hospitals, but has given good results in America. It will be interesting to know what practical advantages it offers in the nursing of respiratory disease and in operating theatres and laboratories. Speaking of the scope of air-conditioning at a conference of distributors held recently at the factory of Frigidaire Ltd., Mr. D. W. Drucquer explained that its extreme application—that of maintaining constant temperature and humidity regardless of outside conditions—was only suitable to industrial process work and was not desirable for living rooms and workrooms, because exposure to the outside air after some hours under rigidly fixed conditions throws too great a strain on the organism for comfort. Ordinary "conditioning for comfort" aims at the maintenance of a certain relation between outside and inside, so as to get a healthy variation within a comfortable range. Some rooms call only for cooling and drying in summer, some only for heating and moistening in winter, some for careful air filtration, and some for conditioning of all kinds. Large industrial and commercial installations have to be carefully thought out and the apparatus chosen by experts in consultation with architects and managers, but the less ambitious "comfort" equipment can be bought as a unit, housed in a casing which can be finished to harmonize with the surroundings. It can stand in a corner out of the way, taking up little more space than a radiator, or it can be suspended from the ceiling. It has to be connected with a water supply, a water outlet, and an electric main, for the principal components are an electric motor and an air compressor. These sets run very silently and cause no disturbance. Air is drawn in by a fan through an oil filter; it then passes over a cooling coil and a heating coil, the activity of which is regulated by a thermostat. Moisture is removed by a drying coil or applied by a spray over the heating coil, both being also under automatic control.

OVARIAN DYSFUNCTION

It is not so many years ago that the pioneers in the study of the influence of the ductless glands on reproduction asserted that the ovary was woman and woman was the ovary. In spite of recent advances in our knowledge of the other ductless glands certain clinical conditions, grouped under the heading of ovarian dysfunction, still account for a high proportion of gynaecological patients. Professor J. P. D. Goodall,¹ in a paper on some aspects of ovarian dysfunction, accentuates four principles. The first is that each patient must be most thoroughly examined, under an anaesthetic if necessary, and that the complete examination should include not only biochemical and pathological tests, but an x-ray photograph of the pituitary fossa. The second is that deficiency of the anterior pituitary reproductive activity during youth leads to failure of development of the uterus and ovaries, whereas in later years it leads to their dysfunction. His third principle is that deficiency in one endocrine gland adversely affects all the other endocrine glands. Fourthly, he states that in the early stages the symptoms of hypofunction of any gland are often indistinguishable from those of hyperfunction. He also stresses the fact that, while emotions are dependent on the secretions of the ductless glands, the glands themselves are largely affected by the emotions, and suggests that in many instances in which endocrine therapy is unsuccessful the reason may be sought in domestic infelicity. In the treatment of amenorrhoea, irregularities of menstruation, ovarian sterility, and certain forms of dysmenorrhoea, menorrhagia, and metrorrhagia Professor Goodall advocates the use of some anterior pituitary preparation. The introductory discussion, however, leads one to wonder whether the improvement noted after the administration of such preparations as emmenin and antuitrin might not have been due to other factors, and whether the time is not ripe for a very carefully controlled investigation, on truly scientific lines, of the effects on human beings of these expensive preparations. In the past similar claims have been widely made for preparations which are now known to be inert. There would appear to be at the moment a risk of the disinterested work of the laboratories and their tentative results being commercially exploited to the great disservice of medicine.

BLOOD GROUPING IN PATERNITY CASES

The four blood groups of Landsteiner enable paternity to be disproved in about one case in six. This average has been doubled by his discovery, with Levine, of the agglutinogens M and N. These authors consider that the heredity of M and N depends upon a single pair of allelomorphous genes. As every blood must contain at least one of this pair there are only three possible phenotypes: any given person's blood can be represented by one of the formulae $M+N-$, $M+N+$, and $M-N+$. The formula $M-N-$ is never found; in almost 20,000 specimens which have been examined by various investigators not one has lacked both M and N. The heredity of these agglutinogens is simply deduced: a child can only possess agglutinogens possessed by one or other parent. If both parents are $M+N-$ their children's blood may correspond to

any of the three formulae. The combinations $M+N-$ parent with $M-N+$ child, and $M-N+$ parent with $M+N-$ child are impossible. Dr. A. S. Wiener,¹ summarizing the results up to date, points out that in 3,487 mother-child relationships no exception has been found to this law. Investigations on 674 families with 1,899 children have presented eight apparent exceptions concerning the father, which must clearly be due to illegitimacy, for the heredity of M and N is independent of sex, and what holds good for the mother must also hold good for the father. Dr. Wiener relates his experience in six cases before the courts. In the first of these a lover was proved not to be the father of a child; in the second, third, and fourth the tests were inconclusive. In the fifth a married woman bore three children during the time she was having relations with a lover; the tests showed that the paternity of the first child was indeterminate, that the lover could not be the father of the second child, and that the husband could not be the father of the third. In the sixth case a putative Group A father, who was alleged to have begotten a Group B child from a Group O mother, was cleared without the evidence of the MN tests. The paternity of five out of the eight children was therefore negatively established—a very useful record. The American courts have been reluctant to use the method, but it is making slow progress. In England it is still practically untried. It must be carried out by an expert, but if it is capable of clearing one man in three who is unjustly accused of paternity it is obviously a valuable form of evidence. It is too much to expect any change in the law by which blood tests might be applied against the will of a defendant, but when lawyers realize that nothing can be proved to a defendant's disadvantage such tests should take their place along with other methods of scientific proof.

THE GRENFELL ASSOCIATION

The recently issued seventh annual report of the Grenfell Association of Great Britain and Ireland has a special interest in view of the presence in this country of Sir Wilfred Grenfell, M.D., F.R.C.S., and of the political and economic situation of Newfoundland. It contains a general survey of the medical work which is being carried on in Labrador and Northern Newfoundland, extracts from the reports of the several centres, and short articles illustrating various emergencies and achievements. The material known as "Grenfell cloth" is becoming a regular source of income to the Mission. Designed originally for the cold climate of Labrador, it is a light, strong fabric, which will keep out wind, snow, and water, and will resist strain and friction. It was proved to be satisfactory in the Mount Everest Expedition last year. It has been found to be of equal value in very hot climates, such as that of Abyssinia, and also by the Mollisons on their transatlantic flight. A new society, the North-West River and District Farming Association, has come into being recently to promote agriculture, to ensure an adequate supply of seed and of vermin killers, and to establish and maintain a wholesome spirit of competition in production. The records of travels in different parts of the territory reveal the immense amount of help that is being given to a most deserving section of British pioneer settlers, whose needs are very great.

¹ *J. Obstet. and Gynaecol. British Empire*, 1933, vi, 649¹ *Amer. Journ. Med. Sci.*, 1933, clxxxvi, 257.

but whose spirit is indomitable. The number of volunteers from Great Britain is increasing. The International Grenfell Association, the governing body of the various Grenfell Associations, links together the allied societies in Canada, the United States, Newfoundland, and Great Britain; the actual work is spread over 1,500 miles of coastline, mostly populated by Anglo-Saxons.

AUSTRALASIAN MEDICAL CONGRESS

The fourth session of the Australasian Medical Congress (British Medical Association) has just been held at Hobart, Tasmania, from January 15th to 20th, under the presidency of Dr. D. H. E. Lines. The scientific discussions were comprised in eleven Sections—namely: Anaesthetics; Medicine; Naval, Military, and Air Force Medicine and Surgery; Obstetrics and Gynaecology; Ophthalmology; Oto-rhino-laryngology; Paediatrics; Pathology, Bacteriology, and Cancer Research; Public Health, Preventive Medicine, and Tropical Hygiene; Surgery; and X-Ray and Electrical Therapy. In addition to the sectional meetings, full sessions of the congress were devoted to the consideration of cancer research and of hospital problems in Australasia. The *Transactions* are to be published in book form. A great variety of entertainments and excursions was arranged.

FOOD OF THE GROWING CHILD

The sixth of the series of Sir Charles Hastings Lectures, inaugurated by the British Medical Association for the purpose of offering to the public information by the highest authorities on matters of general public health interest, will be delivered in the Great Hall of the Association's House in London on Wednesday evening, March 7th. This year's lecturer is Dr. Robert Hutchison, physician to the London Hospital and to the Hospital for Sick Children, Great Ormond Street, and his subject will be "The Food of the Growing Child." The chair will be taken at 8 o'clock by Lord Horder, and after the lecture relevant questions, in writing, are invited. Admission is free, by tickets obtainable on application to the Financial Secretary, B.M.A. House, Tavistock Square, W.C.1. Seats not occupied by ticket holders by 7.50 p.m. will be available for other members of the public.

NUTRITION

The Secretary to the Minister of Health announces that Professor Sir F. Gowland Hopkins, Professor E. P. Cathcart, and Professor Edward Mellanby, as physiologists representing the Minister's Advisory Committee on Nutrition, will confer with Professor V. H. Mottram, Professor S. J. Cowell, and Dr. G. P. Crowden, as physiologists representing the British Medical Association Committee on Nutrition, in regard to the differences which appear to exist between the two committees on the question of the amount of calories and first-class protein appropriate as a basis for suitable diets.

Sir Cuthbert Wallace will deliver the Hunterian Oration before the Royal College of Surgeons of England, at Lincoln's Inn Fields, on Tuesday, February 13th, at 4 p.m.

STERILIZATION OF DEFECTIVES

DEPARTMENTAL COMMITTEE'S REPORT

In June, 1932, following a deputation to the Minister of Health from the County Councils Association, the Association of Municipal Corporations, and the Mental Hospitals Association, Mr. L. G. Brock, chairman of the Board of Control, with the approval of the Minister of Health, appointed a Departmental Committee with the following terms of reference:

"To examine and report on the information already available regarding the hereditary transmission and other causes of mental disorder and deficiency; to consider the value of sterilization as a preventive measure having regard to its physical, psychological, and social effects and to the experience of legislation in other countries permitting it; and to suggest what further inquiries might usefully be undertaken in this connexion."

The committee was presided over by Mr. Brock, and included Mr. Wilfred Trotter, F.R.S., Sergeant Surgeon to the King; Dr. A. F. Tredgold; Professor R. A. Fisher, F.R.S.; Miss Ruth Darwin, a Senior Commissioner of the Board of Control; Dr. R. H. Crowley, Senior Medical Officer of the Board of Education; Dr. E. O. Lewis, a Commissioner of the Board of Control; and Dr. E. W. Adams from the Ministry of Health. Mr. F. Chanter of the Board of Control was appointed secretary of the committee. In the course of its thirty-six meetings the committee took evidence from sixty witnesses, who included representatives of the Royal Colleges of Physicians and Surgeons, biologists, geneticists, psychiatrists, and medical superintendents of mental hospitals and institutions for the mentally defective; the Chairman of Council and the Medical Secretary of the British Medical Association; and representatives of the British Social Hygiene Council and other social workers.

The report, which is unanimous, was presented in Parliament at the close of last week.¹

PRELIMINARY GENERAL CONSIDERATIONS

The highly important matter of the legal position in regard to sterilization, the committee says, is not free from doubt, and in setting out the view which is generally accepted adds the caution that it does not depend on decided cases. It appears to be agreed, however, that while the legality of a sterilizing operation which is necessary for the patient's treatment ("therapeutic" sterilization) is not disputed, operations which are not necessary for the patient's health, but are intended to prevent the propagation of unsound offspring ("eugenic" sterilization), are illegal, whether applied to mental defectives or persons suffering from mental disorder. The legal position in regard to the eugenic sterilization of persons of normal mentality, it says, is less certain, but most authorities take the view that it is illegal.

Another general consideration was the concept of "mental defect," commonly described in terms statutory in origin, and resting upon an administrative rather than upon a scientific basis. The definition in the Mental Deficiency Act, for example, is based upon social adaptability, and the definition in the Education Acts upon educability, and therefore, though the two legal definitions are largely coincident in practice, an appreciable number fall within one definition and not within the other. The committee therefore emphasizes the fact that in this report the term "mental defective" is used to mean a mentally defective individual within the meaning of Section 1 of the Mental Deficiency Act, 1927, unless otherwise stated.

Turning to the extent of the problem, the committee refers to the Wood Committee's estimate (in 1929) of 300,000 as the number of defectives in England and Wales, and says that it is clear that any calculation based on an examination of sample areas, however carefully those areas are selected, is liable to error. Where ascer-

¹ London: H.M. Stationery Office. 1934. Cmd. 4485. (2s. net.)

tainment has been actively carried out the results approximate to the Wood Committee's figure, thus furnishing strong presumptive evidence that the total has not been overestimated. Of this total the Wood Committee calculated that not more than one-third would require segregation in institutes. The number of available beds in the country is still far short of the estimated need, and it may therefore be safely assumed, the committee says, that the number of defectives living in the community—that is, not under custodial care or otherwise segregated—is in round figures a quarter of a million.

Whether the number is increasing, the committee, like the Wood Committee, finds it difficult to say, though the statistics before it left an impression that the incidence of mental defect is on the increase, though not at any rapid rate. But whether the proportion of children born who are or become defective is increasing or not the proportion of defectives alive to-day is larger than it was a generation ago.

PRESENT KNOWLEDGE OF THE CAUSATION OF MENTAL DEFECT

The terms of reference were wide, and the committee wisely decided to restrict its inquiry to those aspects of causation which, in its opinion, had the most direct bearing upon the question of sterilization.

First, as to the evidence concerning the relative importance of heredity and environment. The witnesses who gave evidence all recognized "heredity" as an important factor in the causation of mental defect and disorder. This conclusion, the report says, was based upon the data obtained by the study of family histories of mental patients.

"A substantial, if not indeed a high, proportion of the patients in mental hospitals and in institutions for the mentally defective have one, two, or more relatives who also have suffered from some form of mental disease or defect. If the incidence of mental abnormalities in these families prevailed in all other families of the general community the numbers of mental patients would be considerably larger than the most reliable statistics indicate. This 'familial concentration' is the ground upon which psychologists base their belief that mental disorder and defect are to a great extent inherited conditions."

The mode of transmission of these conditions the committee found to be a more contentious subject, some experts maintaining that several forms of mental disease are transmitted in accordance with Mendelian principles; others, recognizing that the Mendelian theory may explain the transmission of certain specific types, do not think it can account for the mode of transmission of all, and cite the fact that in the same family divergence from the normal appears in different forms; while still others regard that familial concentration alone should not be regarded as adequate proof that mental disease or defect has been transmitted by inheritance.

The committee did not feel called upon to decide between the relative merits of these theories. Much research, it says, will be necessary before a conclusive decision can be reached. For the purpose of this inquiry it was enough to have established that there are many families in which there is an exceptionally high incidence of mental disease and defect, and that in many of these families those conditions are undoubtedly inherited.

"Abstinence from parenthood is the only immediately practicable method of prevention, whether this be obtained by sterilization or by any other means, and in assessing the value of this abstinence the extent to which the disease is familial is of primary importance."

The committee found that investigators of families in which mental defectives occur gave widely varying estimates of the incidence of mental abnormalities in these families. In one respect, however, considerable agreement emerged. The incidence of abnormal mental conditions is definitely greater in the families of the higher-grade defectives than in the families of the lower-grade defectives. Another finding is that families in which there are mentally defective children have other members who,

though not mentally defective, are persons of low intelligence. These findings, it says, suggest that milder grades of mental defect may be regarded as simply poor endowment of intelligence, and, if so, the problem of the inheritance of mental defect is part of the larger problem of inheritance of intelligence. "Highly gifted parents tend to have highly gifted children; dull parents tend to have dull children."

The committee refers to the researches of Dr. Torsten Sjögren into amaurotic idiocy, and also into a special type of defect with well-marked physical signs found to exist in an isolated Swedish valley.

"Sjögren's investigations seem to us to establish that these particular types of defect are inherited, and that amaurotic idiocy of both kinds exhibits the ordinary character of a Mendelian recessive; or, in other words, it may be transmitted by 'carriers' who do not themselves exhibit the defect."

The weight of evidence appeared, however, to be strongly against most defect being of an uncomplicated recessive type. Checking this by what is known of the parentage of recognized defectives, the committee says that the evidence indicates that the proportion of defectives now in institutions, one or both of whose parents can be shown to be defective, is small. This finding, in its view, proves little except that had sterilization been in force for a generation the reduction in the number now requiring institutional accommodation would not have been substantial.

Approach to this problem from another angle caused an inquiry to be made, not into the parentage, but into the children, of defectives. A circular was issued to all mental deficiency authorities calling for information as to physical defects and also to mental age by recognized intelligence tests.

In all 3,733 children were thus examined, the mother being defective in 2,247 and the father in 486 cases. These defectives produced 8,841 children, of whom 2,001, or 22.5 per cent., have died—an abnormally high death rate, too great, the committee thinks, to be due entirely to bad environment and parental inefficiency. As to mental grouping, excluding cases about whom no definite information was available, there were 1,082 children between 7 and 13 years of age, of whom 305, or 16.9 per cent., were classified as defective, and 423, or 23.5 per cent., as retarded. Only twenty-one, or 1.2 per cent., were "superior." In the children over 13, out of a total of 1,848, the number of defectives was 599, or 32.4 per cent., and of retarded 240, or 13 per cent. Taking the two classes together in the first group 40.4 per cent., and in the over 13 group 45.4 per cent., were mentally subnormal.

"When it is remembered that 22.5 per cent. of the children had died, and that these percentages apply only to the survivors, the figures indicate that here we have a social problem calling urgently for some practical preventive measure."

Two more points elicited in this inquiry are noteworthy. One is that neither group indicated an abnormally high incidence of defect or retardation among the firstborn; the other is with regard to the widespread belief in the abnormal fertility of defectives. The inquiry made by the committee and other statistics examined by it completely explode that myth, even though distressing exceptions to the general rule find their way into the Press.

With regard to environment—using the term as covering the period from the fertilization of the ovum up to the time at which mental development is complete—the committee regards it as clearly established that a proportion of cases of mental deficiency is due entirely to environmental factors—for example, injury to brain during birth, inflammation of brain or its membranes after birth, etc.—but that this proportion is comparatively small. On the whole, the committee thinks that between 9 and 20 per cent. of defectives owe their condition solely to adverse factors of the environment. The group of cases in which both morbid hereditary and environmental conditions are present is a much larger one. Lastly, the committee considered in this relation "slum" surroundings; but it could find no evidence that slum conditions in themselves are responsible for causing mental deficiency.

The general conclusions on the causation of mental defect from a committee so authoritative require quotation in full:

1. In many cases of mental defect there exists in the family some form of mental abnormality—that is, insanity, psychoneurosis, epilepsy, defect, or dullness. In the majority of such cases there is evidence of heredity, but the mode of transmission is at present unknown.

2. In the case of certain rare forms of defect, not only is the fact of hereditary transmission known, but the method of transmission has been demonstrated.

3. It is probable that some mental defect is determined by a combination of genetic and environmental factors.

4. Some mental defect is not inherited—that is, the defect is acquired after conception as a result of environmental causes. There is no evidence that such defect is transmissible to subsequent generations.

5. Low-grade mental defect is more frequently associated than is high-grade defect with environmental factors, and it appears to be fairly equally distributed among all classes of society.

6. There is some evidence that conditions operating during the intrauterine period may produce mental defect, but very little is at present known on this point.

7. High-grade mental defect occurs proportionately more frequently in the lowest social stratum than in the rest of the population. In this stratum there appears to be an unduly high incidence of mental defect, insanity, intellectual dullness, epilepsy, as well as tuberculosis and other physical defects. Cause and effect of the conditions found in the social problem group are debatable, but it is possible that selective mating may to a large extent account for this concentration of physical defects and mental defects and disorders. There is evidence that in the poorest districts neighbour marries neighbour, and like marries like.

8. There is no evidence that parental alcoholism is responsible for any appreciable amount of mental defect. Recent research on this matter casts doubt on some of the earlier conclusions based on animal experiments.

9. Our evidence does not indicate any causal connexion between tuberculosis and mental defect.

10. Syphilis is responsible for some, though an undetermined amount of, mental defect.

11. It is impossible in the present state of our knowledge about the causation of mental defect to forecast with certainty whether a child of any given union will exhibit mental abnormalities. It can, however, be shown that, whether the cause be bad heredity or adverse environmental conditions, or both, the children of parents one or both of whom are mentally defective are, on the average, below the normal, and our inquiry shows that nearly one-third of such children as survive are likely to be defective, and more than two-fifths must be expected to exhibit some degree of mental abnormality.

PRESENT KNOWLEDGE OF CAUSATION OF MENTAL DISORDERS

In considering the causation of mental disorders the committee first sets out the difficulties with which it was faced, such as the wide range of mental disorders; the absence of a general agreement as to classification or grouping of mental disorders even within Europe; and the lack of sufficient data or of enough systematic and intensive inquiry into the hereditary and environmental factors which may operate in the production, not of mental disorder in the mass, but of each distinctive clinical type and the need for checking the results against a control group of the mentally sound. There is, however, a considerable body of evidence, mostly derived from foreign sources, relative to certain particular types of mental disorder. These, in the opinion of the committee, justify the following general conclusions.

1. Heredity plays a large part in the causation of mental disorders, though except in the case of Huntington's chorea and myoclonus epilepsy, which are both rare types, there is no conclusive evidence that the transmission follows Mendelian ratios.

2. In many mental disorders other than Huntington's chorea and myoclonus epilepsy the part played by heredity varies widely between different types.

3. Manic-depressive insanity and schizophrenia appear to show a markedly higher familial incidence than other types of mental disorder which are of frequent occurrence.

4. While psychopathic parents tend to have psychopathic children, the view that familial mental instability is usually progressive and tends to become more severe in each succeeding generation is not established. The familial incidence in such cases is not necessarily entirely genetic in origin, since the environmental conditions in which children of psychopathic parents are brought up may tend to aggravate any inherited instability.

5. Familial mental disorder is not necessarily transmitted in the same form, and in many cases what appears to be transmitted is not a specific character, but a generalized predisposition.

6. Where such a predisposition exists the immediate or exciting cause of the breakdown may be of an apparently trivial nature.

7. In a proportion of cases of mental disorder an environmental factor, such as a toxic condition, syphilis, or arteriosclerosis, is the immediate cause and often the only discoverable cause. In some of these cases there is evidence that these environmental factors are associated with an inherited predisposition.

8. There is little evidence that alcoholism is a frequent cause of mental disorder, and in many cases which at present are classed as alcoholic the alcoholism appears to be a symptom of mental abnormality rather than its cause.

RESULTS OF STERILIZATION

The results of sterilization are considered under (a) physiological and psychological, and (b) social results. With regard to the former the committee has been unable to find evidence that in the case of either normal or defective persons any harmful results, either physiological or psychological, ensue upon the operations of vasectomy or salpingectomy. The position in regard to persons who suffer, or have suffered, from mental disorder is more difficult, but the committee accepts the view that the psychological advantages of voluntary sterilization to patients suffering from mental illness would outweigh any injurious results. In such case, however, it considers that sterilization should not be allowed without a recommendation from a competent psychiatrist, who should be required to examine the patient and to certify that in his opinion no injurious results would be likely to follow.

Among (b) the social results expected to follow the adoption of "sterilization of the unfit" and its substitution for the provision of institutional accommodation a considerable monetary saving has held a prominent place.

"This belief, we are convinced, is illusory. Sterilization will not in our opinion reduce to any appreciable extent the present wide disparity between the number of institutional beds available and the best estimate of the number needed. We will go further and say that until sufficient accommodation is provided and ascertainment and community care are better organized, proper use cannot be made of sterilization as a supplementary measure of care for the mentally defective and the protection of the community."

On the other hand, the members of the committee, with one exception, agreed as to the disastrous social and economic results of ignoring defect and of allowing defectives to undertake the ordinary responsibilities of citizenship. "Defectives make inefficient parents. If only for social reasons they should not have children." As regards defectives in institutions, the committee holds that the question of their sterilization only arises when they are considered fit for discharge to some form of care in the community. As to the proportion of patients now in institutions who could be safely released if they were sterilized, experienced superintendents gave estimates ranging from 3 to 5 per cent. The committee thinks it doubtful whether institutional beds will ever be provided or, if efficient community care is organized, will ever be needed for more than a third of the total defective population. If, therefore, there is a case for sterilization it is on numerical grounds more important in relation to the larger number of non-institutional cases.

Among social risks of sterilization which have been suggested is the danger of increased promiscuity and the greater spread of venereal diseases. The committee took pains to ascertain whether in those American States

in which sterilization has mainly been practised any such consequences have ensued. So far as it has been able to ascertain there is no evidence of such happenings. Nevertheless it desires to record with all possible emphasis that:

"The discharge of sterilized defectives, particularly women, may have most unfortunate social results, unless the greatest care is taken to ensure that they receive the constant and vigilant supervision which their mental condition requires. It would be in the highest degree unwise, indeed it might be disastrous, to assume that sterilization will in any way lessen, still less that it will obviate, the need for supervision and after-care."

After a short chapter on Dominion and foreign legislation, the experience of which—with the exception of Alberta, where the results are stated to be "satisfactory" and California, where no evidence was found "that the results of sterilization have not on the whole been good"—is described as "mainly negative," the committee formulates its findings under the heads of general conclusions and recommendations, procedure and safeguards, and operations advised.

GENERAL CONCLUSIONS AND RECOMMENDATIONS

The committee considered compulsory sterilization first, for the obvious reason that if the case for compulsion could be made out there was no need to discuss the less drastic alternative. Assuming that the legislature would not feel justified in compelling any persons to submit to sterilization unless it could be shown beyond reasonable doubt that some, at least, of their offspring would either be mentally defective or would develop mental disorder, it records its deliberate opinion in the following words: "In the present state of knowledge no such proof can be produced." To the question whether there is on scientific grounds an unassailable case for compulsory sterilization it affirms there can be only one answer: "If the test is to be the certainty with which the result of procreation can be predicted in individual cases, the case for compulsion cannot be established."

Further, as a practical measure, the committee doubts the wisdom of compulsion. In the United States of America sterilization has been most practised where it has been administered on a voluntary basis, and general compulsion becomes ineffective without the support of public opinion, while with the support of public opinion it is unnecessary: also any association in the popular mind between mental deficiency institutions and compulsory sterilization might have unfortunate effects both in regard to the admission of children to institutions and to the work of ascertainment. But the real argument against compulsory sterilization is contained in the words quoted above.

Turning to voluntary sterilization, the committee, recognizing the gravity of the case involved, records its view that there are adequate grounds for sanctioning sterilization in the case of defectives and the mentally disordered.

"We know enough to be sure that inheritance plays an important part in the causation of mental defects and disorders . . . and we know also that mentally defective and mentally disordered parents are, as a class, unable to discharge their social and economic liabilities or create an environment favourable to the upbringing of children, and there is reason to believe that sterilization would, in some cases, be welcomed by the patients themselves."

Out of sixty witnesses there was much difference of opinion as to the results which would be attained by sterilization as a measure of social hygiene; but only three witnesses were definitely opposed to it in principle.

At the risk of going beyond the terms of reference the committee, because it felt that it would be both anti-social and inequitable that persons who have good reason to fear that they may transmit to their offspring grave physical difficulties should be left without any remedy except the harassing uncertainty of contraceptive devices, found itself unable to recommend any sterilization scheme limited solely to the mentally unfit, as appears later.

The transmissible physical defects which are sufficiently grave to justify sterilization are easily identifiable, and in certain cases—for example, haemophilia, hereditary blindness, deaf-mutism—the mode of transmission is known. But this is not so in many cases of mental defect and disorder, and the transmission is indirect or through "carriers." The proportion of such carriers the committee thinks it is not far wrong in estimating at ten times greater than are affected persons. The question of carriers thus becomes the crux of the problem, unfortunately as yet not solved. Nevertheless, the committee recommends that the right to sterilization should be extended to all persons "whose family history gives reasonable ground for belief that they may transmit mental disorder or defect."

Then after discussing very briefly some of the objections to sterilization the report passes to the highly important matter of procedure and safeguards.

PROCEDURE AND SAFEGUARDS

The committee considers that the acceptance of a single medical recommendation for eugenic sterilization would put an undue responsibility on the doctor, and therefore proposes two medical recommendations, one from the patient's family doctor and the other from a doctor on a list to be approved by the Minister of Health. If the committee's recommendation to extend voluntary sterilization so as to include also transmissible physical diseases, or carriers of the same, is approved, the list might be divided into two parts, one part containing the names of psychiatrists and the other of general physicians of good standing. The committee is definitely against leaving the approval of practitioners in the hands of the local authorities; such recommendations should be submitted to the Minister of Health, who would, in mental cases, exercise his functions after consulting the Board of Control, who may in certain cases cause the patient to be specially examined.

In order to meet the difficulty of deciding whether or not a particular case comes within the terms of the definition, so justifying sterilization—a difficulty likely to arise in connexion with persons believed to be carriers—the Departmental Committee recommends the appointment of a small advisory committee of doctors and geneticists to whom doubtful cases could be submitted. It stresses the point that the real responsibility must fall upon the doctors who sign the prescribed recommendation, and that no subsequent departmental or Ministerial action can relieve him of responsibility for the consequences of his action. If the doctors are reluctant to accept this responsibility, it declares, the whole system inevitably breaks down. Clearly, it says, Parliament cannot be asked to grant immunity from legal proceedings to the doctor who acts negligently or in bad faith; but the doctors should have the same claim to protection as they have in respect of certificates under the Lunacy and Mental Treatment Acts.

The sterilizing operations advised by the committee are vasectomy for males and salpingectomy for females. As to where the operations should be performed, it sets out reasons why this should not take place at mental deficiency institutions or at mental hospitals.

In a further chapter immediately preceding its conclusions and main recommendations, a summary of which appears below, the committee suggests various fields of research which may throw valuable light upon the problems of inheritance in a wide sense; but this does not lend itself to presentation in abstract.

SUMMARY OF PRINCIPAL CONCLUSIONS

1. Subject to the safeguards proposed, voluntary sterilization should be legalized in the case of: a person who is mentally defective or who has suffered from mental disorder; a person who suffers from, or is believed to be a carrier of, a grave physical disability which has been shown to be transmissible; and a person who is believed to be likely to transmit mental disorder or defect.

2. Before sterilization is sanctioned in the case of a mental defective care should be taken to test his or her fitness for community care.

3. Mental defectives who have been sterilized should receive the supervision which their mental condition requires.

4. The operation of sterilization should only be performed under the written authorization of the Minister of Health, in regard to which the following procedure should apply:

(a) Application for the authorization should be supported by recommendations in a prescribed form signed by two medical practitioners, one of whom should, if possible, be the patient's family doctor and the other a practitioner on a list approved by the Minister. No medical practitioner should sign a recommendation unless he has examined the patient.

(b) The Minister, on receipt of the recommendations, should be empowered to require any necessary amendment of the forms and to cause the patient to be specially examined if it is considered advisable.

(c) In order to deal with difficulties that may arise in connexion with applications on behalf of persons suffering from, or believed to be carriers of, inherited disease or disability, the Minister should be empowered to appoint a small advisory committee, consisting partly of medical practitioners and partly of geneticists, to whom doubtful cases could be referred.

(d) The hospital authorities or (in the case of operations performed elsewhere) the operating surgeon should be required to notify the Minister when the operation has been performed.

(e) In all cases in which the patient is capable of giving consent he should sign a declaration of willingness to be sterilized, and one of the two medical recommendations should include a statement that the effect of the operation has been explained to the patient and that in the medical practitioner's opinion he is capable of understanding it. If the practitioner is not satisfied that the patient is competent to give a reasonable consent, the full consent and understanding of the parent or guardian should be obtained. If the applicant is married he or she should be required to notify the spouse of the application.

(f) In the case of persons who have suffered from mental disorder, sterilization should not be permitted without a recommendation from a competent psychiatrist, who should be required to certify, after examining the patient, that, in his opinion, no injurious results are likely to follow.

(g) In dealing with cases of mental defect and of mental disorder the Minister of Health should exercise his functions after consulting the Board of Control.

(h) The procedure should at all stages be treated as strictly confidential.

5. Medical practitioners, in making recommendations for sterilization, should have protection similar to that accorded to them in respect of certificates given under the Lunacy and Mental Treatment Acts.

6. The operations for sterilization which are recommended are vasectomy in the case of males and salpingectomy in the case of females. The latter operation should only be performed by a surgeon competent to deal with any morbid condition which he may find.

7. The operation of vasectomy should not be authorized in the case of any person who has not reached physical maturity, pending the results of the further research recommended in this connexion.

8. The operation for sterilization should not be performed in a mental hospital or mental deficiency institution.

9. In the case of persons unable to pay the full cost of the operation, the cost (including the expense of the medical recommendations) should be borne by the Mental Deficiency Authority in the case of mental defectives, by the Visiting Committee in the case of persons suffering from mental disorder, and by the Public Health Committee in the case of persons suffering from transmissible physical disorders, subject to the right of the authority to recover from the patients or relatives so much of the cost as is reasonable. In all cases, however, where the cost falls upon local funds, the local authority should have the right to require the patient to enter a municipal hospital or any voluntary hospital with which they may have made arrangements for such cases.

PRACTICE OF EUGENIC STERILIZATION

SAFEGUARDS AND INDICATIONS

A meeting of the Eugenics Society was held in London on January 16th, Sir HUMPHRY ROLLESTON presiding, for the discussion of safeguards in eugenic sterilization.

Dr. R. LANGDON-DOWN said that when the meeting was arranged it was expected that the report of the Departmental Committee of the Ministry of Health would be available, but it was now announced that the report would be published three days later.¹ The Brock Committee, as it was called, was appointed, he thought, because of the movement of public opinion which arose partly as a result of the propaganda of the Eugenics Society, but particularly as a result of the report of the Wood Committee, another Departmental Committee, which had surveyed the problems connected with mental deficiency. The Wood Committee was very half-hearted in any recommendation as to how the evil arising from the propagation of mental defect might be diminished or prevented. The principal opposition to the proposals for sterilization had come from a body specially interested in the welfare of mental defectives; its hostility dated from early days, when the proposals were very different from those now current. In order to sidetrack eugenic propaganda this body adopted the policy that further inquiry as to the cause of mental deficiency was necessary, and the Government thereafter set up the Brock Committee, on which was included one representative of the Eugenics Society, Dr. R. A. FISHER. Dr. Langdon-Down briefly described the nature of the evidence which the Eugenics Society had brought before the Departmental Committee, in particular its citation of German and other foreign experience, which differed from such meagre statistics as had been collected by British workers. This difference appeared on investigation to be due to the fact that in Germany a standard of mental deficiency was taken which was of wider range than was usual in this country. Here we were rather bound by the criteria set up by the Mental

Deficiency Act, which was based on administrative needs, not on biological principles, and in Germany they were rather more free in this respect.

NEED FOR SAFEGUARDS

Dr. C. P. BLACKER said that the question of safeguards, which was the one under consideration that evening, inevitably presented itself when anybody got down to the actual practice of sterilization. It soon became obvious in the course of the society's propaganda that it had to steer an intermediate course between two sets of enemies: on the one flank the apostles of individual liberty, who said that it was entirely a person's private affair whether he was sterilized or not; and on the other those whose attitude was well represented by Dr. Hyacinth Morgan, who, when Major Church introduced the society's Bill into the last Parliament, pictured a self-constituted body of eugenicists sitting on the apex of the social pyramid and dictating to the working woman how many children she might have. By these opponents sterilization was viewed as a potential means of class or racial tyranny. At an early stage the society decided that it would be incompatible with what it took to be British psychology to advocate a compulsory measure. This was not wholly a question of tactics, but those concerned were influenced in that direction by the fact that in those American States which had compulsory and voluntary clauses to their sterilization measures it had become clear that the compulsory clauses were used less and less and the voluntary clauses more and more. If there did not exist in a State a sufficiently strong eugenic or social conscience, the application of compulsion to refractory subjects would lead to appalling difficulties. In the Bill which the society had promoted it was laid down that, in the case of a mentally defective person, the consent of the parent or guardian should be required if the person was unmarried, or, if married, the consent of the spouse, and also the consent in all cases of the Board of Control. A good deal of emphasis was placed upon that last safeguard, for it was felt that, in view of the acknowledged scepticism of the Board of Control with regard to sterilization, one could count on the fact that the Board would not give

¹ See page 161.

its authorization in the case of an individual without excellent reasons for sterilization being done. It was also felt advisable to add the additional safeguard that the operation should be sanctioned by a judicial authority. There was a profound mistrust among the general public of any sort of specialist, and particularly of any board which could be accused of bureaucratic behaviour, so that it was deemed advisable to have, in addition to the consent of the Board of Control, the further sanction of a judicial authority. On grounds of strategy or tactics the Bill was confined to mental defectives, and that was the thin end of the wedge. The thick end of the wedge was not the subsequent surreptitious introduction of compulsory sterilization, but the extension of the voluntary principle to mental convalescents, by which was meant people who had recovered from some recoverable form of insanity, and those who exhibited other transmissible diseases and defects. The words were carefully chosen to cover the social problem group, and it was desired to make the provision such that it would become applicable to the subnormal carrier.

INDICATIONS FOR STERILIZATION

Dr. E. MAPOTHER, medical superintendent of Maudsley Hospital, said that the chief need of the eugenic movement at present was patience. Care had to be taken not to arrest progress and provoke reaction by attempting to replace the present general vetoes by compulsions based on what might be called half-baked science. He confined his remarks to mental disorder, the forms usually called the psychoses. It was only in connexion with the liability to really severe mental disorder or to transmitting such that at present one should advocate the legalization of sterilization. In many instances, he was quite aware, people suffering from neuroses and minor grades of mental inefficiency which quite disqualified them for employment showed an incapacity to limit their families to a size which would be to the interests of the parents, the children, and the State. But the dividing line between minor grades of mental inefficiency on the one hand and normality on the other was almost indefinable, and restriction would be unworkable if the presence of something called a neurosis or a liability to such could be taken as an adequate ground. The first ground for applying sterilization might be called therapeutic, and that included cases in which not only brief periods of strain such as childbirth were apt to produce a breakdown, but also cases in which psychosis arose from severe and prolonged stress, such as fear of pregnancy or the strain of bringing up a family. It was to be hoped that legislation would not interfere with any existing rights to sterilize for therapeutic purposes. The two main grounds for sterilization in connexion with severe mental disorder which really needed discussion had in common the liability of the offspring themselves to be affected with mental disorder. One could be called the truly eugenic ground—that is to say, the tendency to a true inheritance of the psychosis; and there was another possible ground, which consisted in the liability of the offspring to become psychotic rather in virtue of their contact with the psychopathic parent and other stresses occurring during childhood. If one took the evidence for sterilization on these two grounds it rendered the present wholesale veto quite unjustifiable, but the evidence also failed to prove that any form of compulsion would at present be justifiable, and made it plain that voluntary sterilization should be legalized with safeguards. If it was granted that some form of birth control was to be permitted or even encouraged, though not enforced, it would be asked, Why would not contraception suffice for this purpose? The answer was that contraceptive measures to be taken at the time were distasteful to many people, and those who felt in this way, if the permanent sterility of their marriage was desirable, were entitled to have their preferences considered. Moreover, there was no form of contraception which did not at times fail, and the fear of such failure might be prejudicial. Again, contraception was useless in the case of irresponsible persons.

The alleged dangers in connexion with sterilization against which safeguards might have to be provided

were the following: (1) the danger that the application might not be truly voluntary, or thought not to be so; (2) surgical dangers; (3) the danger that one or both of a couple might be sterilized in haste and repent at leisure; (4) the fear that even collaboration between the operator and another doctor, such as was customary in connexion with therapeutic abortion, might not guarantee sufficiently expert opinion as to the chance of psychopathic inheritance; and (5) the danger that if sterilization were legalized in connexion with the liability to the occurrence of severe mental disorder in the offspring this permission might be misused for reasons not within the meaning of the Act. It seemed to him that all these dangers would be met if certain principles were observed. In the first place, the sterilization of one or other party to an actual or intended marriage should be permitted upon the written application of both parties to it, and this on two conditions: the first, that two medical certificates were obtained vouching for the fact that the mating of the two parties was in the light of the best scientific evidence at the time available likely to result in an exceptional proportion of mentally disordered offspring; and the second, that such medical certificates were submitted to an established authority, such as a department of the Ministry of Health or the Board of Control. He believed that in order to ensure that the application was voluntary it should not be permitted in the case of patients under any order sanctioning detention, nor on premises where other certified patients were detained. Not only compulsion, but pressure and the very suspicion of pressure, should be avoided. On the other hand, it should be permitted to those who were carriers of psychopathic inheritance, even though they had never manifested it. The surgical risk could be almost eliminated by giving the central authority power to insist on the operation by a recognized surgeon and in suitable premises. He thought that the operation should be performed on either party to the mating, regardless of which was likely to transmit the tendency. It might be open to the man to be sterilized—the operation being simpler and less dangerous in the case of the man—even though the transmission was through the woman. The danger of frivolous sterilization could be met by the requirement that medical certificates must be submitted to a central authority.

As to the danger that the medical evidence might not adequately guarantee the necessity of sterilization, one certificate might be required from the usual medical attendant of the probable transmitter and the other from a psychiatrist of recognized standing—probably one who held a diploma in psychological medicine. Dr. Mapother did not think that any explicit definition as to what constituted an adequate ground for promoting voluntary sterilization should be attempted. The criteria should be elastic, so that the practice might be progressively adapted to increasing knowledge rather than stereotyped to present knowledge. Only voluntary sterilization in the fullest sense should be undertaken, and that not merely for tactical reasons. Voluntary sterilization was the basis of the practice in Switzerland, where sterilization had been taking place for half a century, and represented almost a model of the way in which it should be done. He thought that the way it was carried out in Nazi Germany illustrated how not to do it. The conditions which in Germany were regarded as permitting compulsory sterilization were mental deficiency, schizophrenia, manic-depressive psychoses, epilepsy, severe alcoholism, and a number of others. His own view about the schizophrenia and manic-depressive psychoses groups was that each was a heterogeneous group, and there were cases which were in a high degree hereditary, and others which were in large measure environmental, for which compulsory sterilization would be totally inapplicable, while the question of voluntary sterilization did not really arise. He understood that the results already seen in Germany, even in anticipation of the recent law, which became effective on January 1st, were disastrous. It rendered liable to sterilization, if not segregated, cases of dementia, schizophrenia, manic-depressive psychoses, and other conditions. It made it obligatory on any doctor diagnosing one of these conditions, even in consultation outside an institu-

tion, to notify the case in the way in which an infectious disease was notified in this country, and such notification, if the patient was not segregated, had to be followed by examination by the court with a view to sterilization. At the same time there had been legalized the castration of criminal sexual perverts, with the result that the two things were being confused and sterilization was being regarded as a punishment, so that diagnosis in private practice was being falsified, and cases of mental disorder were being frightened away from recognized institutions and treated in secret wherever possible. All genuine inquiry as to heredity and accurate information of the sort upon which scientific practice might really be based was becoming quite unobtainable.

In the course of some further discussion, Professor RUGGLES GATES expressed the hope that there would not be an over-elaboration of safeguards such as might unduly diminish the value resulting from any legislative measure in the direction of sterilization. Mrs. C. B. S. HOPSON, a member of the Committee for Legalizing Eugenic Sterilization—a committee set up by the Eugenics Society—gave some account of the practice in Switzerland, where, she said, for fifty years sterilization had been steadily and regularly carried on. There was no legislation except in one canton (the Canton de Vaud), but a considerable amount of social pressure was applied, without legal compulsion, on persons whom the health authority thought required sterilization. In Zürich, out of a population of 400,000, some 400 or 500 women came forward annually for sterilization. Sterilization, whether therapeutic or eugenic, was always undertaken only by a surgeon if two other specialists, one of whom was the recognized chief of psychiatry for the canton, both gave written advice that sterilization was advisable in the particular case. Miss HILDA POCKOCK, a member of the same committee, said that a growing number of people in this country were in favour of a voluntary Bill, especially working-class people who were constantly rubbing shoulders with families of the social problem group. It was unjust, in their opinion, that they should be handicapped by the support of the very large families of the unemployable, and the conviction was growing that the solution was the voluntary sterilization of certain types of people.

England and Wales

Robert Jones Memorial

The *Western Mail* and *South Wales News* of January 16th contained an eloquent message from Sir John Lynn-Thomas in support of the appeal for a national memorial to commemorate the work of the late Sir Robert Jones. In our issue of October 21st, 1933, we recorded the progress that had been made up to that time with the appeal, and announced that the funds would be devoted to the establishment of a Robert Jones lectureship in the Royal College of Surgeons of England, and the institution of a travelling research Fellowship in orthopaedics, to be awarded alternately by the Royal College of Surgeons of England and by the University of Liverpool. "The memorial we want to raise is to the man," writes Sir John Lynn-Thomas. "It was my proud privilege to know him intimately for thirty years, and it is a great joy to realize that Wales is moving to raise a memorial worthy of a noble son." Donations may be forwarded to the honorary treasurers, the Robert Jones National Memorial, Quadrant House, 55, Pall Mall, S.W.1.

Vital Statistics for 1932

Part II of the Registrar-General's Statistical Review of England and Wales for 1932 (Tables, Civil) may be obtained from H.M. Stationery Office (price 2s.). The chief subjects are: population, births, marriages and divorces, migration, registers of electors in England and

Wales; and vital statistics of the British Dominions. A table is given showing the populations of England and Wales, Scotland, and Ireland, as enumerated at each census from 1821 to 1931, and as estimated for each year from 1893 to 1932 inclusive. The population of England and Wales is now estimated to have passed the 40,000,000 mark, having advanced to 40,201,000 as at the middle of 1932, from the 1931 Census figure of 39,952,377. The number of marriages in England and Wales during 1932 was 307,184, against 311,847 in the previous year. Sixteen males and 758 females married at 16, the lowest legal age at which marriages may be solemnized, but in only four cases were the bride and bridegroom both 16 years of age. The number of decrees nisi made absolute in respect of dissolution or annulment of marriage was 3,894, an increase of 130 over the number for 1931. The births registered during the year numbered 613,972, a decrease of 18,109. The consequent birth rate of 15.3 per 1,000 population is the lowest recorded for England and Wales, being 0.5 below that for 1931, the previous lowest, and 1.0 below that for 1930. The only countries showing a lower rate in 1932 were Sweden (14.5), Germany (15.1), and Austria (15.2). The proportion of the sexes in the births registered during the year was 1,050 males to 1,000 females. The statistics relating to Parliamentary electors give the figures for the 1932 Register for England and Wales as 12,440,109 males and 13,999,604 females.

Medical Society of Individual Psychology

The annual dinner of this society was held in London at the Florence Restaurant on January 11th, with Dr. J. C. Young, M.C., in the chair. In proposing the toast of the society the chairman gave a gratifying account of progress, there being now 117 members and associates. Professor Langdon Brown, in proposing the health of the guests, mentioned particularly Mr. McAdam Eccles, Dr. Emanuel Miller, and Mr. Daniel. He paid tribute to Dr. Miller's distinguished work for psychological medicine, but bantered him with being the "mysterius censor" who decided the fate of psychological papers presented to the medical journals. Mr. Daniel's unselfish support of the cause of individual psychology was acknowledged with much cordiality. Mr. McAdam Eccles responded in a humorous speech which drew analogies even from the Loch Ness monster. Dr. Miller spoke of the value of the individual psychology method to medicine and particularly to the general practitioner. Mr. Daniel reported increased sales of the pamphlets, and expressed great faith in their usefulness and further success. Mr. Symons, chairman of the Individual Psychology Club, claimed that it was doing very useful work ancillary to, though distinct from, the Medical Society. Dr. A. Balguy, in proposing the toast of "The Chairman," stated that he and others in general practice were finding their usefulness much increased by the knowledge of the methods of individual psychology.

New Westminster Mortuary

An important public health service has been rendered by the City of Westminster, which has transformed and reorganized its forty-year-old mortuary building at a cost of under £1,500, the design for the conversion having been worked out by the medical officer of health, Dr. A. J. Shinnie. In addition to the improvement of the coroner's court and offices, the largest of the four previously existing rooms has been remodelled as a viewing room and contains the preservation chamber. This refrigerating chamber, of the Kelvinator type, contains nine compartments for bodies. When the doors are closed extracting fans are at once set in motion so that the air is not allowed to stagnate—a very necessary provision in the

case of such decomposed corpses as are recovered from the Thames many weeks after drowning. In one section of the chamber a much lower temperature can be obtained; this has special value in cases of death from certain infectious diseases, and when putrefaction has advanced very far. To the old post-mortem room has been added another of equal size, lit by large lantern lights, but without any louvres, thus obviating the constant down-falling of dust. Ventilation is effected by extracting fans, and good modern equipment for the ample supply of hot and cold water has been installed. In an adjoining small room has been fitted up a pathological laboratory specially designed for facilitating the rapid examination of specimens and their preservation. With this extended accommodation it is now possible to perform four post-mortem examinations simultaneously. Care has been taken also to protect those concerned with viewing bodies from unnecessary distress and unpleasantness, and a specially designed chamber has been introduced for the reception of bodies awaiting burial. Heating throughout the new building is provided by electric tubes.

Ireland

Local Services (Temporary Economies) Bill

This Bill was introduced into the Dail more than four months ago, but its text was only circulated on January 19th. The Bill seriously affects medical officers under local authorities. Section 4, provides that the minimum deduction shall not be less than the minimum deduction under the schedules applicable to civil servants. The section contains the very objectionable provision that the local authority shall consider each case individually instead of in groups, and that it is empowered to make any deduction it thinks proper in excess of the minimum.

Public Health in Westmeath

Dr. Hugh O'Neill, medical officer of health for County Westmeath, in his last annual report states that there has been no change in the sanitary personnel during the year, nor has any advance been made in regard to the attendance of sanitary sub-officers at training courses. Increased pressure of work under the school medical service scheme, involving considerable travelling, has resulted in less time being available for the ordinary public health duties of the county medical officer and for the proper supervision of sanitary sub-officers. It is generally the task at hand, the report continues, which receives attention to the exclusion of other, perhaps equally important, matters, and it is necessary to reaffirm formally the conviction that the appointment of an assistant medical officer will be required, not so much to increase the quantity as to improve the quality of the work which is being carried out. There must be time for organization, for the working out of ways and means, and for the study of various incidental problems which arise if a chief medical officer is to cope in a broad and efficient way with his manifold duties. If this matter has not been emphasized much and often, it is because of recognition of the fact that the present time is not opportune for making a new appointment. In the meantime, the feeling is unavoidable that much remains undone, and that it rests with the future to provide means of reaching a more satisfying and satisfactory standard of public health work in the county. Reference was made in the last report to improvements carried out in the Mullingar water supply in the provision of filtration of the town water. This scheme, which was completed during 1932, also

included the laying of a new main from the intake to the pumping station and the installation of new electric pumps to replace the worn-out oil engines. Filtration, when properly supervised, provides a reasonable guarantee of the purity of a water supply, and samples taken of the filtered and unfiltered water disclosed, on analysis, a very considerable improvement. Housing schemes undertaken by the various local authorities in the county have been adopted with a unanimity which points to the general appreciation of the housing necessities of the people, and to a determination to deal with the problem in a resolute and practical manner. Encouraged by a large grant from the Sweepstakes Fund, the building of a new county hospital at Mullingar was decided upon during 1932. A welcome feature of the new hospital scheme will be the provision of an office for the county medical officer. This will be housed in a separate building, which will also include dental and oculist clinics for the Mullingar area.

Medical Inspection of School Children in Dublin

In a recent annual report on the school medical services for the county borough of Dublin Dr. Mary M. O'Leary, medical officer, states that 140 cases of ringworm of the scalp were found during the year, and the treatment of 112 of these was completed. Of eighteen cases of scabies the treatment of fifteen was carried out. The hospital treatment of ringworm by x rays and thallium is so much quicker than other forms of treatment that school medical officers refer the children to hospitals whenever possible. One case of lupus was found and received violet rays; alopecia, the aetiology of which is still uncertain, was found in fifty-two cases. Children with defective vision numbered 2,952; it is gratifying to note that, of 2,568 cases of defective vision and squint referred for treatment, 2,001 attended eye departments and had treatment completed. In 1,682 cases glasses were supplied, inquiries being made first into the financial position of the parents, most of whom were unemployed. There were twenty-two operations for squint, one for cataract, one for tumour of the eye, and one for cyst on the eyelid; eight artificial eyes were supplied to children who had lost their eyes as the result of accidents. In April a new contract was entered into for the supply of spectacles to school children. Under former contracts the glasses were supplied at a flat rate for spheres, plano-cylinders, and spherocylinders; now the cost of the glasses is calculated on the power of each lens. Some improvements were noted in the hygienic conditions prevalent in certain schools—for example, the installation of electric light and the distemping of walls in light-reflecting colours; the erection of wash-basins; the replacement with bubble fountains of the old-fashioned drinking fountains with metal cup, etc. When referring in other annual reports to the subject of school meals for necessitous children, Dr. O'Leary has stressed the fact that the food given in the homes consists almost solely of carbohydrates, and that the meal provided in the schools should contain such essential food constituents as protein, fat, and vitamin. It has been noted in some, but not in all, of the schools in which free meals are given that these requirements have been fulfilled. In Dr. O'Leary's opinion a hot midday meal is essential for all growing children, as their digestions are impaired by long intervals between meals. A number of children other than those of the necessitous poor have been found on inspection to be suffering from malnutrition. This is not due to lack of food, but is often due to lack of the power of assimilation. The children are too tired in the late afternoon to digest and assimilate food which if given at 12 o'clock or 1 p.m. would benefit them. Also many of the schools are

inadequately heated, and there is no provision for drying clothes in wet weather. A hot midday meal would do much to counteract the effect of this on the children's vitality, and would increase their resistance to infectious and other diseases.

Scotland

Health of Glasgow

In a summary of Glasgow's health statistics for 1933, Dr. A. S. M. Macgregor, the city's medical officer of health, states that deaths during the year numbered 14,748, or 1,320 fewer than in 1932; the death rates for the two years were 13.4 and 14.7 respectively. During the past ten years the death rates have been uniformly low, with the exception of 1929, when there was a serious outbreak of influenzal pneumonia, but the rate for 1933 is the lowest on record, being 0.4 below that for 1923, the vital statistics for which year had hitherto been the most favourable. This low rate, Dr. Macgregor states, may be attributed to the favourable conditions prevailing during the greater part of the year, which resulted in a lower mortality from many causes, especially from respiratory disease. The weather conditions in 1933 were exceptionally favourable from a health point of view, for the rainfall of 29.17 inches was the lowest recorded for over a quarter of a century. The previous lowest rainfall in the returns from Springburn Park was 28.7 inches in 1905; while the lowest since recording was begun there in 1897 was 25.13 in 1902. The hours of bright sunshine numbered 1,255, which is the highest figure since 1919, when 1,341 hours were registered. The mean temperature—48.4° F.—was almost two degrees above the average. Although these favourable climatic conditions, Dr. Macgregor continues, do not influence to any great extent the incidence of infectious diseases, with the possible exception of pneumonia, the year 1933 was marked by reduced prevalence of most diseases except scarlet fever, the incidence of which continued at the same high level as that of 1932. The mortality from scarlet fever, however, was lower, the rate being 76 per million of the population, compared with 93 for the preceding year. Measles was much less prevalent, and indeed was more or less absent during the latter half of the year. This is indicated by a mortality of only 4 per million of the population, compared with 171 in 1932 and 382 in 1931. The death rate from measles has only once before been below 100, and that was in 1929. Whooping-cough, on the other hand, was more prevalent during last winter, and the higher mortality of 204 for 1933 was caused by the incidence of that disease in the early months of the year, into which the epidemic extended. It was not one of the major prevalences, however, for the mortality was less than half that of 1931. The mortality from diphtheria was lower—the rate being 82 as against 109 for 1932—as also was the mortality from cerebro-spinal fever, the rate for which was 72. Only once has the mortality from pulmonary tuberculosis been less than it was last year, and that was in 1930, when the rate was 805; the rate for 1933 was 890. The mortality from non-pulmonary forms of the disease was a record, the rate being 246, as against 269 for the preceding year. Since 1930 there has been a reduction of almost 30 per cent. in the number of deaths from these forms of tuberculosis. Although there was a certain prevalence of influenza in January, it was not one of the major outbreaks of that disease, and the mortality for the year was only 220, compared with 415 for 1932 and 190 for 1931. The mortality from diabetes, nervous and digestive diseases, and nephritis was lower, while the death rate from

senility was only 295, compared with 401 in 1932. On the other hand, the death rate from cancer, heart disease, and arteriosclerosis was higher. Despite the warm spells during the summer and early autumn, the mortality from diarrhoea under 2 years of age was only 319, as against 385 for 1932. Deaths of infants under 1 year numbered 2,062, equivalent to a rate of 97 per 1,000 births; this rate has only been lower on one occasion—1923—when it was 89. The number of births totalled 21,345, giving a birth rate of 19.3 per 1,000 of the population, as against 20.8 and 20.1 for 1932 and 1931 respectively; this low birth rate is also a record for the city.

Edinburgh Dental Hospital

At a dinner held on January 15th, in the Royal College of Surgeons, Edinburgh, Dr. William Guy, who recently retired from the post of dean of the Edinburgh Dental Hospital, was entertained by his colleagues and friends in the dental profession. Mr. A. Ernest Miller, who presided, said that Dr. Guy had been dean of the Dental Hospital and School from 1899 to 1933, and had given evidence of great personality, singular individuality, and competence. The work he had done for dental education was known to most of them. He had banned chloroform, which was the general dental anaesthetic when he first became dean, and he had also banned the great array of dental forceps; nowadays most people extracted with the two pairs of forceps which he had devised. By his foresight, organizing ability, and administrative power the hospital had risen from insignificance to an institution worthy of the profession and of the city. In reply to the toast of his health, Dr. Guy outlined the history of the Edinburgh Dental Hospital. The institution, he said, began in January, 1860, as the Edinburgh Dental Dispensary, and was known by that name until 1878, when the present name was adopted. At that time the hospital moved to No. 18, Brown Square, and the equipment then consisted of three Fox chairs with three spittoons and brackets. In 1899, when he was appointed to the vacant office of dean, he found the premises to be inadequate and the equipment deplorable; also there was no money to spare. Now the hospital had buildings, equipment, and funds to the value of between £30,000 and £40,000, and there were more than one hundred pupils in the work-room. The Scottish Branch of the British Dental Association, Dr. Guy stated, began and maintained the agitation which resulted in the Dentists Act, 1921, and which, in turn, established the Dental Board.

East Fortune Sanatorium Extension

It was stated at a meeting of the East Fortune Public Health Committee on January 16th that an extension of East Fortune Sanatorium was required, and that it was proposed to make an addition sufficient for the accommodation of twelve patients and four extra nurses at a cost of £10,760. At present there was accommodation for 200 patients, the sanatorium serving the needs of seven counties. As patients from East Lothian occupied fifty beds, the cost to this county of the addition would be one-quarter of £10,760. It was mentioned that it might be necessary to appoint an extra assistant medical officer.

As a memorial to his cousin the late Dr. Alfred Eichholz, chief inspector under the Board of Education, Mr. William Eichholz has offered to equip a new massage clinic in London. The offer was made to and has been accepted by the National Institute for the Blind. The new clinic will be established near the headquarters of the Institute in Great Portland Street, W. Dr. Eichholz devoted his leisure to the care of the blind and deaf. He was a member of the council of the National Institute for the Blind, and served as chairman of its education and research committee.

CORRESPONDENCE

The Report on Sterilization

SIR,—It appears that there are a number of persons, even some within the profession, who, probably quite unwisely, attach importance to my opinions with regard to the report of the Departmental Committee on Sterilization. As some of those opinions, reported at second hand, have not been recorded with strict accuracy, perhaps you will allow me space to state them—but not on this occasion to argue about them—more carefully.

In the first place, and in general, the report seems to me to be an admirable and valuable document. While it should not, of course, be regarded as an authoritative statement on all aspects of its subject, it is undoubtedly an excellent and impartial summary of "the information already available regarding the hereditary transmission and other causes of mental disorder and deficiency," the primary business with which the Committee was charged. It is gratifying to find close agreement in this respect with the British Medical Association's Report on Mental Deficiency.

In particular, the report contains certain observations and pronouncements which strike me as specially opportune and important in a document intended for wide publicity. Such are: (1) that there is no ground for alarmist views with regard to racial deterioration (p. 9); (2) that there is no definite line separating mental defect from dullness (p. 12); (3) that "the dismal chronicles of the Kallikaks, the Jukes, and the Nams" are of no scientific value (p. 13); (4) that the proportion of defectives with certifiably defective parents is small, and that therefore had compulsory sterilization of defectives been in force for a generation the reduction in number would not have been substantial (p. 14); (5) that the majority of the surviving offspring of parents one at least of whom is mentally defective are not subnormal (p. 17); (6) that there is no evidence of excessive fertility among defectives (p. 18); (7) that it is impossible in the present state of knowledge to forecast with any certainty whether a child of any given union will exhibit mental abnormalities (p. 21); (8) that the belief that sterilization will serve as a substitute for institutional provision is illusory (p. 30); but that approximately two-thirds of all defectives are capable of life in the general community (p. 32).

I find myself in complete agreement with the Committee in regarding the objections to a general policy of compulsory sterilization as conclusive, and also in its opinion that the case for legalization of voluntary sterilization in some classes of case, and with proper safeguards, has been made out. One is particularly grateful to the Committee for stating so emphatically that any legal provisions should not be restricted to mental defect and disorder, but should extend to certain grave physical disabilities, and that the operation should never be performed within an institution for mental defectives.

I differ, however, from the conclusions and recommendations of the Committee, of course with great respect and with a mind still open to argument, in two matters of major importance. First, I regard the field which it thinks appropriate for voluntary sterilization as in several respects too wide. Secondly, I have no sympathy, either logically or sociologically, with the contention that sterilization should be adopted, or more readily acceded to, in the case of mentally defective persons on the ground that they might or would perform the duties of parenthood imperfectly. Both these points need discussion. With regard to the former I will only say here that, whereas the Committee would include (1) all persons suffering from the defect, and (2) all persons who believe themselves to be carriers of the defect though not manifesting it, I would

include only (1) persons suffering from the defect in whose case it was proved (or at least highly probable) that the cause was inherited and transmissible, and (2) carriers of a defect known to be transmissible and of which the mode of transmission was likewise reasonably certain. The difficulties and risks of certification and sanction in many cases in the more restricted field would be formidable; in the wider field large numbers of cases would, I believe, in the present state of knowledge, be impossible of determination and sociologically and eugenically questionable. The very recommendations of the Committee for further research prove this. With regard to the second point of difference, there are many persons other than mental defectives who make imperfect or undesirable parents, to an extent fully as injurious to the children, and it would be wholly unjust and impolitic to single out defectives even for voluntary sterilization on this ground.

I should like to add, as is obvious, that I have confined myself in this letter to those parts of the report which relate to mental deficiency and not to mental disorder; and that the profession will note with satisfaction that the suggestions made by witnesses from the British Medical Association for the safeguarding of medical practitioners in relation to certificates have been recommended for acceptance by the Departmental Committee.—I am, etc.,

London, N.W., Jan. 20th.

HENRY B. BRACKENBURY.

Inheritance of Mental Deficiency

SIR,—Professor Ruggles Gates's letter (*Journal*, January 20th, p. 129) takes it for granted that "insanity" is inherited by organic channels. As I pointed out some weeks ago in the *Journal* there is no unequivocal evidence that this is so. On the contrary, the advocates of the "inheritance theory" have given their view the benefit of every doubt, and have even, on one memorable occasion, twisted mathematical reasoning to suit their purpose.

Professor Gates supposes that a feeble-minded man could not join the Army, get a job on a boat, or drive a cab. I have known quite low-grade feeble minds do more than this. He finds it "quite possible" that the child who died at 2½ "was a mental defective"! If another child had been born also mentally defective, then the fifty-fifty ratio between defective and normal (which accords with the "simplest assumption" of the eugenisists) would have existed. But should such a child have been born, and, unfortunately, have turned out to be normal, the resources of eugenisist advocacy would still not be exhausted. We should then have a clear case of the twenty-five/seventy-five ratio of Mendelian recessiveness, and it would still be evident that the condition vaguely labelled "mental defect" is germinally inherited! A simple supposition may elucidate eugenisist logic in this matter. Suppose the incestuous couple had had sixteen children (and, after all, defectives are notoriously prolific), then the evidence for Mendelian inheritance would depend upon how closely the ratio between affected and normal children conformed to one of the known Mendelian ratios. But which of the arithmetically possible ratios is not "Mendelian"? What possibility is there that the facts, whatever they may be, could not be made to fit the eugenisists' contentions? None.

The "probable error" in the assessment of the incidence of qualities so indefinite as mental defect or insanity might be as high as 25 per cent. As this also is tendentiously manipulated, we can easily see how the advocates of genetic interpretations find the environmental factors "hardly worthy of serious consideration."

—I am, etc.,

London, W.C.1, Jan. 19th.

IAN D. SUTTIE.

Hereditary Blindness and Other Defects

SIR,—One reads Mr. Myles Bickerton's mass of scientific material relating to blindness with some respect, only to find the cure-all remedies open to question. The efficacy of certain fashionable panaceas put forth by our profession is rapidly exceeding that of the better-known patent medicines. I submit that the animal-herd attitude towards our fellow beings, be they afflicted or well, is not common to the whole profession. I submit, further, that it is possible that gonococcal ophthalmia may be as effectively wiped out by the elimination of unsuitable gonococci as by the prevention of unsuitable births.

Mr. Bickerton finds myopia a subject of some import, one forming a considerable proportion of blind days lived. Setting aside the myopic parents, who may be put in the category of spilt milk, being already productive and therefore beyond redemption, we find that, of a given total of 850 children, 300 were myopics. Of these, 200, coming from tainted stock, are better eliminated. Taking only the progeny of ninety-one non-myopic matings, there are but 25 per cent. of myopic children. Since each type is myopic, and therefore a potential breeder of a myopic brood, we may assume that what is good for the one is also good for the other. We are supplied with constructive measures by which myopia may be eliminated. Applying these, only so far as the problem concerns the progeny of ninety-one non-myopic control families, we may ask which of the following measures is to be adopted: constructive birth control, sterilization, abortion, euthanasia, segregation, control of marriage, Wassermann reaction, or deportation to Vera Cruz for the opinion of an enlightened Government? However, the matter is of little moment, affecting but 25 per cent. of the children of the non-myopic breeders (ignoring the percentage of potential grandbreeders of myopes).

Listening to the buzzing of a personal bee, I now turn to my own corner of medicine. Various authorities tell me that familial, congenital, and hereditary influences are bountiful with most of my everyday problems—to mention but a few: deaf-mutism, progressive deafness, choanal atresia, cleft palate, nasal "catarrh," ozaena, and so on. We otologists must claim to add our quota to the Vera Cruz cargo. The psychiatrist—if not obsessed by other notions—will naturally expect a goodly share of human fodder. Again, can we justly withhold a modicum from the physician, the orthopaedist, the tuberculosis officer, the dermatologist, even the gynaecologist? Any residuum will doubtless be claimed by the toxicologist and the balneologist. My apologies to any ologists who may feel neglected. The surgeon will be too busy tying ligatures round the vas to bother about his due share of the queue outside.

A little care is necessary, for Bennett of Nebraska tells us that migraine is first cousin to epilepsy. I and a proportion of my colleagues will doubtless consume our fifteen grains of aspirin in manner covert, lest we be led to the theatre for a bilateral dose of catgut instead. Yet may we fail to escape the flood of progress, despite all care, and some day an endless stream of jobless guardian angels, queued outside the Celestial Unemployment Bureau, will look down to see the chairman of the World Sterilizing Committee ligaturing the only other occupant of Earth—that is, the chairman of the World Birth Control League. The hydrocephalic dictator of Vera Cruz has by this time been birth-controlled before conception, the Supreme Arch-abortionist having died prematurely from unsuspected dysgenic causes. From this time onward the *Micrococcus catarrhalis* reigns supreme, as yet uncontrolled by the birth control of omniscient man. Truly is *Alice* in Wonderland considered a great classic!—I am, etc.,

Newcastle-on-Tyne, Jan. 27th.

F. MCGUCKIN.

The New Cancer Problem

SIR,—Please allow me to comment on Mr. Hastings Gifford's letter and his courteous allusion to a statement I made. In dealing with a subject so vast and complex, it would be wise to state to which particular part or parts of it reference is being made. Perhaps I should have been more specific in this respect.

The "cancer problem" is encyclopaedic, and includes primary themes and thoughts, some of which are within and others appear beyond the reaches of our souls. Some observers might consider the problem a solved one when the prevention, cure, and inducing agent have been discovered; whilst others might reflect that there are factors that still remain untouched.—I am, etc.,

London, W., Jan. 22nd.

G. LENTHAL CHEATEE.

Continuous Intravenous Saline

SIR,—The valuable article by Messrs. Bailey and Carnov on the above subject, and subsequent correspondence, are full of interest. I should not join in, except that Dr. Herbert Spencer's letter brought back to my mind that large intravenous injections for combating the effects of severe haemorrhage were used prior to the publication of his cases in the *Lancet* of 1892. Reference to the *Lancet* of December 30th, 1882, will disclose a record of two very interesting cases, published by me at that date, which occurred during my tour as resident accoucheur at the London Hospital. From time to time I have employed similar methods since.

These were by no means the first cases in which the practice of treating post-partum haemorrhage by the instillation of saline fluid had been employed. The publication of these cases elicited a very interesting commentary by the late Dr. Robert Barnes, then obstetric physician at St. George's Hospital (see *Lancet*, January 7th, 1883, p. 137). The perusal of these reports, which give an idea of some of the orthodox methods in vogue fifty years ago in the treatment of post-partum haemorrhage, makes one shudder.

What marvellous advances have been made during the last half-century! None more notable than the many uses now made of intravenous medication, of which salvarsan and its substitutes provide a striking example.—I am, etc.,

Manchester, Jan. 16th.

WILLIAM COATES.

Surgeons' Certificates after Abdominal Operations

SIR,—It seems rather surprising that many people, after having undergone an abdominal operation or operations, should be so ignorant or forgetful of what has been done by the surgeon. It is a common experience to meet patients uncertain whether their appendix or gall-bladder has been removed, or, in the case of women, oblivious as to how much of their generative organs they still possess. One can hardly expect patients to make a written note of what they may have been told by the surgeon, and probably the majority are quite content to let their surgical adventure sink into the mists of reminiscence.

It may be difficult to obtain the information from other sources, for surgeons and physicians retire or die, case notes disappear, and even hospitals—more especially the smaller ones—cannot always supply it. As such information may be of great importance not only to the patient but to some physician or surgeon under whose care he has come at a later date, it seems reasonable that a more accessible source of information should, if possible, be available, and to meet this the following suggestion is

put forward. Surgeons, after performing an abdominal operation, should give to the patient or other responsible party a brief written statement of what has been removed, what anastomosis has been made, or anything else they think might be useful for future reference. The actual condition found need not be specified, and in the case of operations at hospital, the surgeon might be relieved of this extra work by one of his qualified subordinates.

It is because cases do occur where it is difficult or even impossible to ascertain, except perhaps by some further examination, what has been done surgically that the suggestion is made—though not without some hesitation, as we are already overburdened by an increasing number of compulsory certificates. Possibly some surgeons do this already as a matter of routine, while others may consider it undesirable for various reasons, but it is difficult to see how patients, who, after all, are chiefly concerned, would be other than benefited if such a course were adopted or, at any rate, adopted more generally.—I am, etc.,

London, W 1, Jan. 19th.

R. W. A. SALMOND.

Painful Injections

SIR,—Dr. Bousfield's letter in your issue of January 13th (p. 76) raises an interesting point, for with a really sharp needle subcutaneous or intravenous injections should be almost painless if the fluid injected is non-irritating. I have noticed, however, that even with the most meticulous care over the needle-point patients sometimes complain of the injection hurting, and have come to the same conclusion—namely; that an infinitesimal amount of spirit in or on the needle was the cause of the pain.

The boiling of needles and syringes easily obviates this difficulty, but is open to the following objections: (1) The needles very soon cease to be really sharp. (2) Repeated heating and cooling of syringes causes a warping of the glass, so that the smooth and air-tight action that is so delightful, and in intravenous therapy so necessary, is lost. This is less manifest with all-glass syringes, but very common with the metal-and-glass variety of the Record type, and I suspect that the reason why hospital syringes are usually so appalling to use is that they are subjected to repeated and prolonged boiling. (3) Spirit cases, for the carrying of hypodermic syringes, etc., are deservedly too useful in private practice to be abandoned.

My present practice is as follows: All needles, syringes, lumbar puncture instruments, and cutting instruments which cannot be boiled are either kept or immersed for twenty minutes before use in the following solution: lysol max, ether 5ij, sp. vini indust. to 1 pint—in which they do not rust, and which, with the exception of the aromatic odour, is, I suspect, of similar composition to "surgical spirit." This solution is very irritating, and care is taken to wash the instruments thoroughly in sterile water before use—in the case of syringes the water being drawn up and expelled through the needle two or three times. Should boiled water not be available, filling the syringe through the needle two or three times with ether will wash out all spirit. A few strokes of the piston will then evaporate the ether, leaving one with a dry, sterile syringe and needle.—I am, etc.,

Brighton, January 17th.

L. I. M. CASTLEDEN.

SIR.—I have been very interested in the observations of Dr. Bousfield (January 13th, p. 76) and Dr. Loewy (January 20th, p. 124) because I have for some time practised a technique in the giving of injections which I am assured gives rise to little or no pain. I had

observed that whenever an injection was followed by bleeding it had invariably been a painful one, and, conversely, that when no bleeding followed there had been, as invariably, a minimum of pain. I therefore resolved to avoid causing any bleeding when giving an injection, and whenever I have succeeded in this there has always been little or no pain.

My technique consists in holding the skin fairly tense and observing it closely in a good light. In most cases a fine mottling of the skin will be observed, in which the darker areas correspond to the vascular network and the paler areas to the avascular interstices. It is into the centre of one of these avascular areas that I insert the needle. The avascular areas are extremely small—no bigger than a small pin's head—but they are quite apparent after a little practice, except in certain skins, notably those which are very white and the more fashionable sun-tanned.

I have always used industrial spirit as a sterilizing agent, and I believe that what little spirit remains upon, and in, the needle becomes so diluted in the filling of the syringe that it can be disregarded.—I am, etc.,

S. F. DURRANS, M.R.C.S., L.R.C.P.

Broadstone, Dorset, Jan. 20th.

Legal Ownership of X-Ray Films

SIR,—Your article on this subject in the *British Medical Journal* of January 13th raises several interesting points. Briefly, you state that a court of law would be likely to make its decision according to the existing custom of the profession, and you suggest that it is not customary for a radiologist to hand over x-ray films to the patient. If we admit that the existing custom is likely to prove the deciding factor we must show that this procedure is generally adopted and recognized.

I always send the x-ray films and report on a patient direct to the medical practitioner concerned. If I did not do so the great majority of medical men would be dissatisfied. I usually do not see them again. If I insisted on their being returned a large amount of trouble would be caused through forgetfulness, etc. A certain number of practitioners retain the films themselves, but in this area I believe the majority hand them to the patient. One practitioner remarked to me: "I always give a patient your films, but never the accompanying report." I feel convinced that some similar procedure is adopted in a large number of places. Patients who come to see me for electrotherapy frequently remark that they have been x-rayed at various periods in the past in other places, and that they have their films, and I find it unusual for a patient to admit having been x-rayed without being given the custody of the skiagrams. Just as a practitioner would not be satisfied if he were not sent the films in the first place, so a large number of patients would be aggrieved if they were refused them subsequently. Human nature being what it is, we all try to please people when we can reasonably do so.

In certain instances a radiologist will take two films, retaining one himself; or, alternatively, he may make a print or a reduction, keeping either this or the original; but I am sure that there are very few who do not send either a film or a print to the patient's doctor, and I am equally convinced that a very large proportion of patients are subsequently presented with the films. From the above observations it would appear probable that a court of law would find that there was no universally accepted custom in this matter, or that it was usual for a patient to be presented with his films subsequent to his examination.—I am, etc.,

Ipwich, Jan 15th.

C. H. C. DALTON.

"Under the Influence of Drink"

SIR.—In the *Times* of January 9th Lord Knutsford appeals, under the above title, for more suitable punishment of motor drivers convicted of accidents causing bodily injury whilst under the influence of drink. Would it not be possible to go further and endeavour to diminish the appalling toll in death and injuries due to this cause? The public are not interested in the dangers of alcohol as detailed by reformers, often more zealous than truthful, for many generations; but need biased propaganda deter an attempt to diminish in some measure this terrible price of modern transport? If it were possible to get a better perspective into the public mind regarding the action of alcohol something might be gained. But having been told that it affects judgement and diminishes efficiency, which experience has shown them it does not do in any material degree which affects their lives, the public is sceptical of statements of that kind. The all-important action of alcohol from the point of view of motor driving is its effect on attention. Professor Mellanby has taught us that 10 c.cm. of alcohol can be metabolized per hour by the human body, but half this quantity taken hour by hour diminishes attention. Deliberate judgement is not seriously affected even by relatively large doses of alcohol. An action which may require only the fraction of a second, however, probably is very sensibly affected. Notwithstanding the published papers and even monographs on the effect of alcohol on reflex actions, etc., the action of this substance on attention requires further investigation, especially on a large scale and from the point of view of emergencies in motor driving and similar occupations. And the purpose of this letter is to ask the Medical Research Council or other competent body to consider the undertaking of such large-scale experiments. I will willingly become a volunteer for my age group and submit to any experiments conducted in London, Oxford, or Cambridge that may be decided upon. If it were found that alcohol diminishes efficiency in mechanical emergencies a wise use of the fact by a proper authority might deter some men from drinking before driving.

One other point. The methods of determining the degree of drunkenness seem still to be an appeal to the speech and the legs. It is surely not impossible to devise some simple, cheap, and foolproof apparatus, capable of being kept at most central police stations, which would graphically record the efficiency of the driver of a wayward car whom the police might consider a danger to the public. That result might be an outcome of the investigation suggested.—I am, etc.,

Salmon, Jan. 13th

C. R. MARSHALL.

Ætiology of Goitre

SIR.—It is with much interest that I have read Sir Robert McCarrison's able article on "Food and Goitre" (October 14th, 1933, p. 671). It is of particular interest to me, as in October, 1912, I read a paper before the Victorian Branch of the British Medical Association, which was published in the November 9th issue of the *Australian Medical Journal*, on "The Necessity of Lime in the System and its Relation to Goitre." I had been living in Southern Victoria, where goitre was very prevalent and was of the toxic variety. I found that during confinements these cases usually flooded. There was practically no lime in the district, and the cattle developed "the cripples," akin to rickets. The children, having to milk cows all their lives, disliked milk and rarely took it. The water supplies were rain water in galvanized iron tanks, which towards the end of the summer were very low, and whose bacterial content was extremely high, almost enough to poison them. There was much to suggest that

calcium was very deficient in their lives, and when put on calcium lactate they showed a wonderful improvement. Goitres improved, symptoms diminished, and all flooding ceased. The locality was coastal, so one assumed there was ample iodine. Feeling that both calcium and iodine were mixed up in the goitre question, I undertook some research work at the Melbourne University under Professor Osborne, and evolved a method for estimating the blood calcium, as at that time there was no workable method extant. After a lot of work a satisfactory method was established.

Rabbits were fed on a diet free from calcium, and some were given thyroid extract as well. These showed marked increased vascularity at the epiphyseal ends of the bones, which suggested that the bones were being called upon to supply the calcium necessary for the blood. This and the fact that calcium was needed, both as free ions as well as in colloidal combination, raised the question as to the value or otherwise of a blood calcium estimation. At the same time work was done on colloids, as in some goitres there is a retention of colloid and in others the vessels are found empty, showing that the rigidity of the colloid is liable to vary. Normally the colloid retains the iodine supply of the body till called upon for use. If it should be too thin it will not be retained and will be extravagantly wasted; if too thick to be brought into the circulation, it will collect and the body will be starved of iodine supplies, showing, on the one hand, signs of thyrotoxicosis, and, on the other, myxoedema. Not only may there be a shortage of available calcium, but once excessive thyroid activity starts there is increased excretion of that mineral. Colloids are dependent upon calcium and iodine for the state of their rigidity.

The experiments done in this connexion, though not conclusive, together with many clinical observations, were suggestive enough to make one feel that the thyroid controlled the viscosity of the blood and body fluids. Viscosity experiments done with capillary tubes showed a reduction up to 25 per cent. in the blood of exophthalmic and thyrotoxic goitres. The action of thyroid extract in getting rid of the colloid oedema of myxoedema is presumably due to the reduction of its viscosity by the thyroline. Hence the diuresis. The firmness of the clot in myxoedemias and the delayed clotting period in exophthalmic goitre were well known to those who had dealings with such.

These latter views were read before the Congress here in 1924, and because they were totally different from everybody else's—who were all quite satisfied that lack of iodine was the one and only cause of goitre—they received scant attention. At the same time these views were put forward as only dealing with a certain part of the process, for by this time it had been established to my own satisfaction that goitre could be cured by the removal of infections, and as no other form of treatment could do so, it must necessarily play a large part in the causation of it. I would like to suggest that where excess of fat tends to produce goitre there is a danger of calcium starvation, owing to combination of fatty acids with calcium salts forming insoluble soaps which are not broken down by the action of the bile. Some fatty acids form more insoluble soaps than others; that formed from cod liver is perhaps one of the most soluble. Prior to 1912 I had recognized the adrenal exhaustion in cases of hyperthyroidism, and treated all such cases accordingly.

It is surprising the number of organisms and toxins that are capable of producing goitre. Farrant found that abrin and ricin, as well as many bacterial toxins, when injected caused goitre. The gonococcus is at times responsible. Infusions of excreta and the drinking water from the tanks in Gyp land are both bacterial infections or toxic poisons. How far the lack of vitamins is responsible for goitre in Victoria is hard to say, but of this we are sure, that goitre can be cured by removal of infections together with adequate supplies of calcium, and very rapid results are obtained when the calcium is given internally, especially in thyrotoxic cases. At last we

can feel that the riddle of the causation of goitre is nearly solved, and the iodine bogy pushed into the background.

Briefly, the picture can be summed up thus. The normal mechanism of the thyroid is disorganized in the majority of cases by direct invasion of bacteria or gross toxic poisoning. The thyroid colloid is the storehouse of the iodine of the body. It is held in a certain state of rigidity ready for immediate use. This is largely governed by the calcium-iodine balance. Should the colloid be too thin it will not be retained, but constantly poured into the system, causing hyperthyroidism. In the effort to rectify matters calcium will be stolen from the bones, and so the body gradually becomes depleted; the iodine is used up, hence the need for more. To meet the demands the thyroid is called upon to do extra work, and hypertrophies in the process. Should retention of colloid be established, owing to too rigid a colloid, hypothyroidism will result till enough iodine is supplied to reduce its rigidity and so make it available. Clinical evidence strongly supports these views.—I am, etc.,

Melbourne, Victoria, Nov. 30th, 1933.

SYDNEY PERN,
M.R.C.S., L.R.C.P.

Rest in the Treatment of Neuroses

SIR,—The question of whether or not rest in bed is indicated in the treatment of a neurosis is a separate problem for each individual case. In the majority of cases I think one must give a negative answer, and there are many sound reasons why it is in the best interests of the patient that he should continue to lead a normal life. The exhaustion which Dr. Astley Cooper mentions is certainly an obvious symptom in many cases; but the cause of it is that the patient is exhausting himself by mental conflict. By putting the patient to bed the physician is throwing the weight of his authority on the side of the Unconscious factors which are striving to get the patient to withdraw from his efforts at adaptation. Once in bed the patient finds himself back in the infantile position of irresponsibility which his Unconscious has desired. Many of my patients have confessed to me that the happiest periods of their lives have been the time spent in nursing homes when undergoing some operation.

In my experience conditions for a cure are much more favourable when the physician uses his prestige to aid the patient to struggle against this regressive attitude. The relief of unburdening himself to someone whom he feels to be understanding and sympathetic goes a long way towards relieving the patient's anxiety and consequent exhaustion.—I am, etc.,

Birmingham, Jan. 16th.

R. MACDONALD LADELL.

The "Schoolboy's Heart"

SIR,—I was much interested by Dr. Cassidy's mention of "schoolboy's heart" in his article in the *Journal* of January 13th (p. 45). He does not go into the question of the cause of these patients' effort syndrome. My view of this—possibly the same as his own—may be worth mentioning, since it suggests an alternative line of treatment for those patients whom reassurance has failed to convince. These, in his hands, are probably negligible, but not in everybody's, as the patients who find their way here show.

The cause, I have found, is to be sought in the abdomen, even in those who complain of neither indigestion nor constipation. They do, however, complain as a rule of pain about the lower left ribs, and show some epigastric tenderness and excessive resistance to lateral compression of the left, but not the right, lower ribs. These signs result from a spastic pylorus and a dilated stomach; the former maintains the latter, which, in its turn, causes a

rapid pulse by its upward pressure's embarrassing the heart's action. Cessation of symptoms and a marked reduction in the pulse rate are produced in a few days by massage calculated to overcome the spasticity of the pylorus and then to diminish the volume of the stomach. The rapid subsidence of his symptoms and the demonstrable reduction in his pulse rate after the manipulations can hardly fail to convince a patient that his trouble is due to an easily remediable mechanical defect in the working of his stomach. Once fear is relieved, the emotion responsible for the failure to relax the pylorus is no longer operative; thus there is very little tendency to relapse.—I am, etc.,

London, W.1, Jan. 13th.

J. H. CYRIAC.

Birth Control Clinics and Cases of Sterility

SIR,—With reference to the review of the medical report of the Society for the Provision of Birth Control Clinics, in the *British Medical Journal* of January 13th, I should like to point out that cases of sterility are examined and, where necessary, are referred to hospitals or private practitioners for treatment. A recent analysis of our first eight thousand cases shows that thirty patients came on account of sterility. The financial position of this society makes it necessary that treatments should be limited to patients requiring contraceptive advice; facilities for other treatments are available elsewhere. The object of this society is primarily to give birth control advice and instruction which is not yet adequately provided in the existing medical services.—I am, etc.,

London, S.E.17, Jan. 16th

GLADYS M. COX.

SIR,—In the *Journal* of January 13th there was an annotation commenting on the annual reports of the Society for the Provision of Birth Control Clinics and of the National Birth Control Association. In it the following sentences occur:

"There are married women of the poorer classes who want guidance not as to how they can best reduce their liability to become pregnant, but how, if possible, they may overcome the sterility which distresses them. Ought not the staffs of clinics, especially of those established or aided by national or municipal funds, to be as ready to help the one woman as the other?"

At the women's welfare centres of which I am medical officer, and at which cases recommended and paid for by the local city and county health authorities are dealt with, an increasing number of sterile women come to the clinics each year for advice and help. To the best of my knowledge this has always been looked upon as part of the doctors' work at the clinics connected with the Society for the Provision of Birth Control Clinics; indeed, it is very definitely part of its programme of constructive birth control.—I am, etc.,

Crediton, Jan. 18th.

MARGARET C. N. JACKSON.

M.M.S.A. and D.C.O.G.

SIR,—The notice in your issue of January 20th concerning the institution of the diploma of the College of Obstetricians and Gynaecologists is somewhat misleading in that it would appear to suggest that up to the present no provision had been made which embraced the objects of the new diploma and the ground covered by the proposed examination. May I therefore be allowed to recall that the diploma of Mastery of Midwifery of the Society of Apothecaries, examinations for which have been held twice yearly since 1928, was in like manner designed to assist the public health authorities and others in the selection of practitioners who have made a special study of, and proved themselves expert in, ante-natal care, obstetrics, and infant welfare?

The public health side of the examination for the Mastery of Midwifery was further strengthened by the introduction last year of a special examination paper on "public health aspects of maternity and child welfare," which is set and marked by examiners of wide experience holding public health appointments. The examination, therefore, now has three written papers (obstetrics, paediatrics, and public health aspects) followed by full oral and clinical tests, and candidates are not admissible unless they are on the British Register and have held a registrable diploma for at least three years, and have complied with the regulations with regard to the appointments they have held.—I am, etc.,

HENRY COOPER,
Group Captain R.A.F.

London, E.C.4, Jan. 22rd. Registrar, Society of Apothecaries.

British Health Resorts

SIR,—I greatly doubt whether the medical profession has realized the present condition of the British Health Resorts Association, in spite of the letters that appeared from "Spartan," Dr. Collis Hallowes, and Dr. Alfred Cox. It is so serious that I venture to ask you to allow me to put the facts once more before your readers.

This association has only been kept in being by the fact that a few people, laymen and medical men, have subscribed freely to its funds. They and those others who have given so generously of their time to the very strenuous committee and other work that has been involved stand outside the benefits that the association can confer. The backing we have had from the medical profession has been all that we could ask. Every prominent medical body in the country has not merely given us its blessing, but deputed valuable and important members to form part of our committees and to help us in every possible way.

On the other hand, the pecuniary support we have received has been far less than we had hoped for and expected. We have been living from hand to mouth, and have had the greatest difficulty in paying the modest salaries for the valuable help we have had from our secretary and from our small paid staff. To the excellence and devotedness of their work I would like to pay a high tribute. If financial support is not forthcoming we shall be obliged to close down, for those who have hitherto provided it feel that it is not up to them to continue doing so, but that it is the duty of all those who will profit most abundantly by the movement—and among these I include not merely the doctors, but the towns, the transport services, and all those who cater for amusements or necessities in any form. We have convincing proof that where we have held conferences the towns have been benefited, and those concerned have unhesitatingly attributed this increased prosperity to our work. Our new handbook, with Dr. Fortescue Fox as its editor, will shortly be in the hands of the public, and we know that it will provide both the medical profession and their patients with a fund of valuable information which has not hitherto been available.

I appeal most urgently to the medical men in every place to which our invalids are sent to help us now. They can do so in two ways: (1) by joining the association and paying its very modest annual subscription of one guinea (through our secretary, Dr. Alfred Cox, at 199, Piccadilly, W.1); and (2), and more materially still, by actively interesting all with whom they come in contact on the urban, municipal, and other boards in our movement, which is a national one. We were told at our recent annual meeting that if the public only knew how good the movement was they would back it. It is up to the medical men to let them know. It has been abundantly shown that we have in Britain all the facilities for treating

a very large number of our invalids, but if this is to be done successfully there must be most careful and methodical organization. It has been estimated that if we could be sure of an income of between £2,000 and £3,000 a year we could launch out into work that would greatly foster the development of our health resorts. Surely this is not a big amount to pay in order to keep back in this country a serious fraction of the thirty million pounds a year which it is computed is being taken out of it by our people going to foreign resorts in search of health and pleasure. If we can weather another year Dr. Cox believes—and so, I think, do all of us who are working with him—that we shall be established. *Bis dat qui cito dat.*—I am, etc.,

London, W.1, Jan. 15th.

R. H. ELLIOT,
Chairman of Council, British
Health Resorts Association.

Serum Reaction for Malignancy

SIR,—Regarding the recent correspondence in the *British Medical Journal*, the Cronin Lowe modification of the Bendien test has been carried out at the Royal Institute of Public Health during the past nine months, using the Zeiss interferometer and, latterly, the Adam Hilger interferometer. Through the courtesy of Dr. Cronin Lowe advantage was provided of observing the complete detail in his laboratory, and, in spite of this, it was found that practical experience was so necessary that the first fifty results were regarded as of no other value than to perfect us in the technique. It should be noted that other workers are not all carrying out exactly the "Cronin Lowe" technique—his method of shaking the tubes and of mixing serum and reagent does not appear to be absolutely adhered to by some of the correspondents. Unless the method is carried out on more uniform lines criticism cannot be securely founded.

It would appear that a test of such importance, which claims to give some extra light on the diagnosis and cause of malignancy, has been dismissed too summarily by some of the correspondents, and that an insufficient number of tests have been carried out for mature judgement. It may be that the test in its present state is not applicable to general routine work; certain aspects of the technique depend too much on personal factors, and even such a precise instrument as the interferometer presents difficulties. Some 160 tests have been carried out at this Institute—even so, it is not considered that a definite conclusion can be arrived at.

The following important points arise in this connexion: Can it be said at present what constitutes a normal serum for the test? An apparently normal person's serum may give a malignant factor. If, in years to come, this individual develops cancer, has the test shown the predisposition or lack of "something" which will inhibit malignancy? A clinical diagnosis is not absolute, and even a tissue examination may not always be read truly. Is it not possible in some cases that positive serums with apparently clinical negative cancer diagnosis may eventually prove clinically malignant? Does the non-fasting blood give false readings? It would appear that the test can only be accurately judged after observation of a series of patients over a prolonged period of time, in order to verify many diagnoses and to test the sera of apparently normal individuals over a similar prolonged period.—I am, etc.,

E. G. ANNIS,
London, W.C.1, Jan. 9th. Acting Principal, Royal Institute
of Public Health.

P.S.—Since writing the above I note in the *British Medical Journal* of January 6th that Dr. C. J. Stocker of Lancaster has had similar experience and makes somewhat similar observations. His comment as to 1,700 tests is apt.

A "New" Type of Influenza?

STR.—It may be of interest to mention that in North London during the last fourteen days a new clinical type of influenza (as far as we are aware) has presented itself. The initial cases caused a little anxiety on account of their lack of definite signs and continued pyrexia.

The clinical picture, typical in almost every case (twenty in all have been seen up to the present), was as follows:

The patients complained of swelling of the face, confined chiefly to the upper half over the supraorbital regions and eyelids. Puffiness of the lower lid was marked. In a high percentage there was chemosis and congestion of the conjunctivae, with increased vascularity. At this stage the patient was afebrile. Within six to twelve hours headache, malaise, and feverishness, with moderate perspiration, were complained of, and the temperature and pulse rate were increased, typical findings being a temperature of 103° F. and a pulse rate of 120. The tongue was dry and coated with a dirty white fur. General physical examination was negative.

Acute nephritis was the tentative diagnosis arrived at in the early cases, but routine examination of the urine showed complete absence of albumin and blood in all cases.

Symptoms, with the addition in some cases of a slight hacking cough, continued from two to five days up to a week in severe cases.

This type is particularly resistant to treatment. Pulv. ipecac. co. and acid. acetylsalicyl., which we have used extensively in the past with success, was almost ineffective and tended to aggravate the lassitude. The most effective combination of drugs seems to be acid. acetylsalicyl. grains x, phenacetin. grains v, caffeine grains ij. Pyrexia in most cases began to fall within twelve hours, and there was a corresponding relief in the symptoms. Within two to five days temperature and pulse rate were normal and the symptoms had disappeared. A subdued light in the sickroom or an eyeshade gave considerable relief to the eye condition. Frequent bathing with lot. acid. boric. was also helpful. Treatment apart from this was carried out on general principles.

I should be interested to hear whether other members of the profession have met with a similar condition.—I am, etc.,

JAMES L. S. THOMSON, M.B., Ch.B.

London, N.22, Jan. 17th.

Obituary

DR. WILLIAM ACKRILL STAMFORD, who died recently at the age of 93, had been in practice at Tibshelf, Derbyshire, for more than half a century. A native of Beverley, he was a student of the old Leeds School of Medicine, and qualified M.R.C.S.Eng. in 1833. In his early days Dr. Stamford was well known as an athlete and rider in point-to-point races, and he claimed to be the first Englishman to ride the old "bone-shaker" bicycle. He founded the local Ambulance Brigade at Tibshelf, which appeared for a command inspection by Queen Victoria at Windsor Castle, and in 1900 the Prince of Wales (afterwards King Edward VII) presented to Dr. Stamford on behalf of the Queen the long-service ambulance medal. Dr. Stamford was a prominent Freemason, and was twice Master of the Tibshelf Lodge, which he founded.

Dr. CHARLES RANDOLPH of Milverton, Somerset, died on January 14th, at the age of 83 years. He had practised in Milverton, and over a very large area of the district, for more than sixty years. He studied medicine at the Bristol Royal Infirmary and at St. Bartholomew's Hospital, London, qualifying M.R.C.S.Eng. in 1871, and obtained the L.R.C.P.Ed. in 1872. From that time he took over his father's practice, and carried it on until his retirement in 1931. Dr. Randolph belonged to the British Medical Association for the whole of his career, and was president of the West Somerset Branch about forty-five years ago. He held the appointment of medical officer of health to the Wellington Rural District Council from

1874 to 1931, and was Poor Law medical officer for the same period. His sole interest in life was his profession, and never once during his long career could he be persuaded to take any holiday for more than a couple of days, and even that rarely. His patients declared that his very presence in the sickroom carried confidence and comfort with it. He can best be described as a true friend of the poor, and was in fact the old type of family doctor and counsellor.

Universities and Colleges

UNIVERSITY OF LONDON

Lectures

A course of six lectures on cytology will be given at University College by Dr. R. J. Ludford, Dr. E. S. Horning, and Dr. K. C. Richardson, on Wednesdays, February 7th to March 14th, at 5 p.m. Dr. Ludford will deliver the first three lectures on "The Physical Properties of Protoplasm," "Vital Staining, the Reaction of Cells to Dyestuffs," and "Tissue Culture as a Technique for the Study of Living Cells." The fourth and sixth lectures will be given by Dr. Horning on "Micro-incineration" and "The Enzymatic Function of Mitochondria and the Significance of the Golgi Apparatus," and the fifth lecture will be delivered by Dr. Richardson on "The Secretory Phenomena in the Oviduct of the Fowl." The lectures will be followed by demonstrations of microscopical preparations, and are open without fee to students of the university and others interested in the subject.

UNIVERSITY OF DUBLIN

At the later winter commencements in the Hilary Term, held in Trinity College on January 17th, the following medical degrees were conferred:

M.Ch.—F. W. G. Smith (*in absentia*).

M.B., B.Ch., B.A.O.—D. S. Torrens (*stip. cond.*).

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-ON-TYNE

A special course of post-graduate instruction has been arranged for the months of January, February, and March. A course of lectures by Dr. J. C. Spence, followed by a clinical demonstration of cases, at the Royal Victoria Infirmary and Babies' Hospital, Newcastle, on Thursdays at 4 p.m., began on January 25th. A series of ten meetings dealing with pulmonary tuberculosis and infectious diseases is being held at the City Hospital, Walker Gate, Newcastle, on Wednesdays at 6.30 p.m. The fee for each special course is £3 3s.

Classes for clinical instruction in medicine and surgery, or lecture-demonstrations, will be held at Newcastle General Hospital every Sunday at 10.30 a.m. until March 25th. There is no fee, and all medical practitioners are invited to attend.

The Services

DEATHS IN THE SERVICES

Lieut.-Colonel Edward Surman Peck, Bengal Medical Service (ret.), died at Montreux, Switzerland, on January 15th. He was born on March 23rd, 1866, the son of William Bishop Peck, Esq., wine merchant, of Westbury, Gloucestershire, and was educated at Cambridge, where he graduated B.A., M.B., and B.S. in 1891, and also took the D.P.H. in 1894. Entering the I.M.S. as surgeon lieutenant on January 29th, 1894, he retired, on account of ill-health, as major on December 6th, 1913, but was subsequently promoted to lieutenant-colonel while serving in the war, on December 11th, 1916. He served on the North-West Frontier of India in the Chitral Campaign of 1895, took part in the relief of Chitral, and gained the frontier medal with a clasp. In 1913 he took an air pilot's certificate. He rejoined for service in the war of 1914-18, from October 19th, 1914, serving for a short time in a hospital ship, and then in the Indian Hospital at York Place, Brighton, from its opening in November, 1914, to its closure on December 31st, 1915. He was then sent to India, but was invalided after a few months. He was married, and was a brother of the late Lieut.-Colonel F. S. Peck, I.M.S.

Surgeon Commander Edward Henry MacSherry, M.D., M.Ch., R.N. (ret.), died at Eastbourne on January 4th. He graduated M.D., M.Ch., and M.A.O. in the Royal University of Ireland in 1886.

VITAL STATISTICS FOR ENGLAND AND WALES, 1933

We are indebted to the Registrar-General for the following statement regarding the provisional birth rates and death rates, and the rates of infantile mortality, in England and Wales and in certain parts of the country, during 1933. The statement is issued for the information of medical officers of health.

ENGLAND AND WALES
Birth Rate, Death Rate, and Infantile Mortality for the Year 1933 (Provisional Figures)

	Live Births per 1,000 Population	Deaths per 1,000 Population (Crude Rate)	Deaths under One Year per 1,000 Regis- tered Live Births
England and Wales	14.4	12.3	64
118 county boroughs and great towns, including London	14.4	12.2	67
131 smaller towns with estimated resident populations of from 25,000 to 50,000 at 1931 Census	14.3	10.9	56
London (administrative county)	13.1	12.5	79

The birth and death rates for England and Wales as a whole are calculated on the estimated mid-1933 population, but the remaining rates are calculated on the estimated mid-1932 populations.

For the fifth year in succession the birth rate is the lowest on record, being 0.9 per 1,000 below that of 1932 and 1.4 below that of 1931.

The death rate is 0.3 above that for 1932, and is the same as that for 1931. The infant mortality rate is 1 per 1,000 below that for 1932, and, with the one exception of the year 1930 (6), is the lowest on record.

Medical News

The Hunterian Society's banquet to commemorate the 206th anniversary of the birth of John Hunter will be held at the May Fair Hotel, Berkeley Street, W., on Thursday, February 8th, at 7 for 7.30 p.m. The guests of honour will include Lord Horder, Judge Cecil Whiteley, K.C., and Sir Charles Batho.

The Royal Sanitary Institute will hold a sessional meeting at Newport, Mon., on Friday, February 9th, in the Town Hall. At 5 p.m. papers will be read on "The Spread of Infectious Diseases," by Dr. J. Greenwood Wilson, medical officer of health, Cardiff; on "The Changing Outlook on the Control of Infectious Diseases," by Dr. H. W. Catto, medical officer of health, Newport; and on "The Housing Acts and the Need for Standards and Definitions," by Mr. C. J. Burr. The chair will be taken by Professor R. M. F. Picken.

The seventh annual meeting of the Association of Clinical Pathologists will be held at St. Mary's Hospital, Paddington, W., to-day (Saturday, January 27th), at 9.45 a.m., when there will be a discussion on the prognosis in meningitis.

A paper on the canning industry will be read before the Royal Society of Arts, John Street, Adelphi, W.C., on Wednesday, February 28th, at 8 p.m., by Mr. T. N. Morris, M.A., of the Low Temperature Research Station, Cambridge, with Professor E. F. Armstrong, F.R.S., in the chair.

A new post-graduate course opened at the National Hospital, Queen Square, W.C.1, on January 22nd, and will be continued till Friday, March 23rd. The course includes out-patient clinics, lectures and clinical demonstrations on each weekday, except Saturday, at 2 p.m. and 3.30 p.m. respectively; demonstrations on the pathology of the nervous system on Wednesdays and Thursdays at 12 noon; demonstrations on the anatomy and physiology of the nervous system on Tuesdays at 12 noon; and demonstrations on neurological ophthalmology on Mondays at 4.30 p.m. The fee for the course is £10 10s., and for clinical clerks or those who hold perpetual tickets, £8 8s. Special arrangements will be made for those who cannot take the whole course.

A three months' course of instruction in modern methods in the diagnosis and treatment of venereal diseases will begin at the Salford Municipal Clinic on Thursday, March 1st, at 11 a.m. Its main purpose is to

enable those attending it to obtain the Ministry of Health certificate. The fee for the course is two guineas, payable in advance. Those desirous of enrolling must send their names and addresses by February 19th to Dr. E. T. Burke, Municipal Clinic, 155, Regent Road, Salford, 5, Lancs.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the third of Dr. Clark-Kennedy's lecture-demonstrations will be given on January 30th at 2.30 p.m., and will deal with organic dyspepsia; the fourth, on February 6th, with vomiting and haematemesis. There will be a week's course in neurology at the West End Hospital for Nervous Diseases, from February 5th to 10th, occupying the whole of each day. A course in gynaecology will be given at the Chelsea Hospital for Women from February 5th to 17th, and a week-end course in physical medicine at the London Clinic and Institute of Physical Medicine on February 10th and 11th. A whole-day course in diseases of the chest will be given at the Brompton Hospital from February 12th to 17th. Four demonstrations on ante-natal treatment will be given by Dame Louise Mellroy at the Royal Free Hospital at 5 p.m. on February 16th to March 9th, and six demonstrations on the interpretation of pyelograms by Dr. Mather Cordiner, at 8 p.m. on Tuesdays and Fridays from February 13th to March 2nd. Courses arranged by the Fellowship of Medicine are open only to members and associates unless otherwise stated.

On Friday, February 9th, at 3.30 p.m., the new nurses' Home provided at the London County Council's hospital in Baneroff Road, Mile End, will be opened by the chairman of the Central Public Health Committee of the Council, Dr. F. Barrie Lambert.

A conference on atomic physics, to be opened by Lord Rutherford, will be held in 1934, under the auspices of the Physical Society. The details of the programme are not yet settled, but the conference is expected to last over two days at least, and some of the meetings will probably be held in London and some in Cambridge.

The committee of the Cancer Hospital, Fulham Road, London, has awarded a scholarship of the value of £100 per annum to Mrs. Boyland, B.A., in recognition of her services in the Research Institute of the hospital. She has investigated with Dr. E. Boyland the respiration of normal and cancerous tissues in the presence of derivatives of cancer-producing compounds, and will continue the development of this work. Mrs. Boyland had previously carried out research work at Cambridge, Heidelberg, and the Royal Institution.

The editorial board of the *British Journal of Anaesthesia* is offering a prize of £15 for the best essay on any subject directly connected with the physiology or practice of anaesthetics. The competition is open to any person holding a qualification within the British Empire. Essays must be not less than 2,000 and not more than 6,000 words in length, and written or typed on one side of the paper only. They must be submitted on or before August 31st to the Editor, at 29, St. Andrew's Mansions, Dorset Street, W.1. The editorial board will be the sole judges of the competition, and reserve the right to publish in the journal any or all of the essays submitted.

Lord Nuffield (Sir William Morris) has given £45,000 for the erection of a new block of private wards at Guy's Hospital. His donations to hospitals and charities now amount to over £750,000.

The issue of *Forschungen und Fortschritte* for January 10th contains an appreciation by Dr. Joachim Hammerling of the Kaiser Wilhelm Institute for Biology, Berlin, of the work of the biologist Gregor Mendel on the occasion of the fiftieth anniversary of his death.

The issue of the *Bulletin de l'Académie de Médecine* for December 12th contains a eulogy of the eminent scientist Prince Albert of Monaco, who died in 1922, by the general secretary, Professor L. Aehard.

Dr. W. O. Sankey has been promoted to the rank of regional medical officer under the Ministry of Health.

Professor Forsell of Stockholm and Professor Nolf of Liège have been elected corresponding members of the Académie de Médecine.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUESTIONS AND ANSWERS

Threadworms

"GLEVUM" would be glad of advice how best to treat threadworms in an adolescent. Is quassia wood in powder ever given internally?

Treatment of Bacilluria

Dr. G. A. GARRY SIMPSON (London, W.2) would be glad to learn of the experience of others in the treatment of bacilluria with preparations of lactic acid bacilli.

Skull Measurements

Dr. KATHLEEN VAUGHAN (London, W.) writes: What is the average measurement in adult man of the *suboccipito-bregmatic* circumference of the skull? It varies considerably among civilized people (greater difference in size among their heads than among native tribes).

Oysters, Calories, and Food Prices

Professor J. A. NIXON writes with reference to Dr. Edward Cross's note (January 20th, p. 131) to say that Professor Dodd's figures are correct—namely, 88 calories for one dozen oysters. Professor Nixon wishes also to amend his statement of what 1s. will buy: 12 oz. butter yields 360 grams of fat, not 300; and 3,240 calories, not 3,600. In Bristol, he adds, 1s. would buy 1 lb. of beef without bone.

Income Tax

Change in Practice—Cash Basis

"C. R. C." disposed of his share in a partnership (A) as from October 31st, 1933, and acquired a share in a smaller practice (B) as from November 16th, 1933. He is told that either he must pay tax on the money received from his old practice after he left it or must state the amount of the debts due to that practice as at January 1st, 1932, and December 31st, 1932—figures which it is now very difficult to ascertain. Other points mentioned by "C. R. C." will be apparent from the answer below.

* It is not stated whether an election has been made by the past and present members of partnership A to have the practice regarded as having ceased and been restarted at October 31st, 1933. If it has, the revenue authorities are entitled to have evidence of the correct amount of the earnings for the year and nine months subsequent to January 1st 1932, and the cash basis (which is correct in the long run but not necessarily over a short period) is not really appropriate. If, however, such an election has not been made—the more usual course—"C. R. C." is merely liable to account for tax on half of his share of the full partnership assessment on A. In neither case is he liable to account for tax on post-October, 1933, receipts as such. As accounts in firm B are usually made up to March 31st, nothing would be gained by changing the date.

The tax demanded as payable on January, 1934, is due for the year ending April 5th, 1934, but is normally calculated according to the income of the year 1932—or the year to March 31st, 1933.

LETTERS, NOTES, ETC.

Treatment of Chilblains

"R. C." writes: As there has been much correspondence about chilblains in your columns these observations on one of my cases may be appreciated. The patient, a female, aged 27, with marked pes cavus in her right leg, has for many years suffered during each winter from a large chilblain on the back of the lower third of her right leg. The chilblain has always occupied an area of several square inches, where the skin is blue and cold, and there is local oedema. At times, pruritus has been severe. The chilblain has been "broken" in some previous winters. The left leg is quite normal; there are no varicose veins. Her job is sedentary, but she gets abundant exercise—cycling, etc.—at week-ends. Last winter I treated her with kalzania, calcium lactate, and cod-liver oil. Iodex was rubbed in locally. I also gave the usual hygienic instructions about thicker stockings, etc. This treatment was practically ineffective. This winter I treated her by covering the area with elastic adhesive bandage (not encircling the leg), the strips being applied under tension to reduce the oedema. No internal treatment was given at all, and the dressing was left on for a month unchanged. During this period there was no pruritus, and on removal of the dressing the condition was improved. The patient is completely satisfied with the treatment, and I have put on another similar dressing.

Childbirth at 50 Years of Age

Dr. E. L. BUNTING (Worcester) writes: The following note of a case of childbirth at the age of 50½ years may be of interest. Mrs. P.; born on July 18th, 1873, married for twenty-eight years, and having two daughters, aged 26 and 24 respectively, was delivered by me of a bony male child, weighing 11 lb., on December 1st, 1923. The labour lasted thirty-six hours on account of early rupture of the membranes, and delivery was completed by low forceps. I took some trouble to verify the patient's age, and although this was not entered in the register of births for the district where she was born, I wrote to the vicar of the parish, who replied as follows: "The lady was baptised with her brother on January 4th, 1874. Date of her birth is not given. Double christening is in favour of the child being some months old at baptism. It looks as if the family has been looked up by a visitor from the church, and the two children brought to be christened together. This often happens." I also wrote to the patient's eldest brother, who replied as follows: "My sister was born July 18th, 1873. There is an entry in the family Bible, from which I have taken it to forward to you." I think this can be regarded as pretty conclusive evidence as to the patient's age, and I can say her appearance was that of a woman over 50.

Memorial to Philip Edward Glynn

The parents and sisters of the late Philip Edward Glynn, F.R.C.S., resident orthopaedic officer at Leeds General Infirmary, ask the hospitality of these columns to express their deep gratitude to his friends, colleagues, and patients at Leeds and elsewhere, who joined with them in endowing a child's cot in the Orthopaedic Department of Leeds General Infirmary in affectionate remembrance of him. The cot was dedicated by the Rev. P. D. Robbins, A.F.C., on January 12th.

A booklet, *Modern Cooking Methods in Modern Hospitals*, has been issued by the British Commercial Gas Association, and copies can be obtained free from the secretary of the association, 28, Grosvenor Gardens, London, S.W.1.

A folder, giving brief particulars of the Hot Springs, Bath, has been issued for the use of the medical profession, and copies may be had from Mr. John Hatton, the Spa director, at the Pump Room.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 39, 40, 41, 44, 45, and 46 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 35.

A Paper
ONSOME PRACTICAL POINTS IN THE TREATMENT
OF PULMONARY TUBERCULOSIS BY
ARTIFICIAL PNEUMOTHORAX

BY

A. LISLE PUNCH, M.B., M.R.C.P.

SENIOR PHYSICIAN, ROYAL NORTHERN HOSPITAL, AND PHYSICIAN TO
THE BRIMPTON HOSPITAL FOR CONSUMPTION AND
DISEASES OF THE CHEST

The idea of treating pulmonary tuberculosis by collapsing the diseased lung was mooted as long ago as 100 years. Except in isolated cases it was not carried into practice until in 1894 Forlanini and Murphy of Chicago introduced it as a therapeutic measure. It remained comparatively neglected until Branner, Spengler, and others took it up and employed it in the treatment of pulmonary tuberculosis on an extensive scale. It was not till some years after the war that English physicians realized its value, and it is only in the last fifteen years or so that it has been widely used in Great Britain.

Although we have the experience of some fifteen years with which to form some estimate of its value and the type of case in which it is applicable, yet even now there is no unanimity of opinion on either point, even among those whose experience is sufficiently wide to render their opinion of value. We meet with all shades of opinion. At the one extreme there are those who maintain that it is valueless in any case, and at the other those who would urge it in every case as soon as a definite diagnosis of tuberculosis of the lung is established. "It would appear that the truth lies midway between these extremes, and that although, as Sir James Kingston Fowler has truly said, "artificial pneumothorax is the only advance in the treatment of pulmonary tuberculosis since the introduction of sanatorium treatment as carried out at Nordach," yet the advance, great as it is, is only applicable in something like 5 per cent. of cases. Ninety-five per cent. of sufferers from pulmonary tuberculosis have still to be treated by the old methods of diet, hygiene, and climate. Very great care must be taken in selecting cases for this treatment if it is to maintain its place as the valuable therapeutic measure which all the available evidence, if carefully sifted, indicates that it is. It is not an easy matter to be dogmatic and to lay down hard-and-fast rules for guidance as to the suitability or otherwise of any particular case for artificial pneumothorax treatment. No two cases of pulmonary tuberculosis are identical, and the interpretation by the physician of what he finds clinically, or by the radiologist of what he sees, is subject to so great a personal variation that all that can be done is to indicate on broad lines the chief factors that must be considered in determining this point.

UNILATERAL DISEASE AS A CRITERION

Only those cases in which the disease is unilateral or mainly unilateral are suitable for pneumothorax treatment. At this stage it might appear unnecessary to stress so obvious a point. There are still, however, not a few who would urge collapse of the worse side when the disease is bilateral, or who would, when it is impossible to determine which side is the worse, induce partial collapse of both sides simultaneously. With regard to the latter procedure—that is, bilateral simultaneous artificial pneumothorax—it is difficult to see any justification for it either in theory or judging from such results as are available. Collapse of the worse side when there is appreciable disease on the contralateral side has not in my hands, nor in the hands of many other observers,

yielded good results. Considerable disease on the contralateral side is therefore a definite contraindication to collapse therapy.

*Determination of Presence or Absence of Disease on
the Other Side*

In arriving at a decision in this matter two important points must be borne in mind.

1. The fact that no abnormal physical signs can be detected in the contralateral lung does not indicate that there is no disease in it. It is well recognized that a radiogram of a tuberculous lung will nearly always show more extensive disease than the physical signs indicate, and may indeed show infiltration of the lung where no abnormal physical signs are demonstrable.

2. The presence of crepitations at the contralateral apex does not of necessity indicate the existence of disease at that site. Not infrequently such crepitations are conducted from the opposite side. Here again an x-ray is the only reliable means of deciding the point.

It should be clear, therefore, that a radiogram is essential in determining whether a case is unilateral. It may be asked—and indeed often is—whether the x-ray is a reliable means of detecting or excluding active pulmonary tuberculosis. For practical purposes it may be affirmed that when there is an active tuberculous lesion in the lung the x-ray will show infiltration of the lung tissue, and that the absence of such infiltration can be taken to indicate no such lesion. Instances are occasionally met with of patients who are undoubtedly suffering from active tuberculosis of the lung (as proved by the presence of tubercle bacilli in the sputum) whose radiograms are negative, at all events on one occasion. Such cases are, however, so extremely rare that the absence of infiltration in the radiogram on the contralateral side can be taken for the purpose under consideration to indicate unilateral disease. The reading of x-ray pictures of the lung is by no means easy. Prolonged study and considerable experience are necessary for the correct interpretation of the significance of the shadows seen in the radiograms of the chest. Unfortunately, there are many radiologists who are quite prepared to give a definite opinion as to the presence or absence of tuberculosis in the lungs who have neither given that study nor acquired that experience which is essential for their opinion to be of value. It can be definitely stated that x-ray pictures of the lungs, when properly interpreted, are the most valuable means of diagnosis of pulmonary tuberculosis that we possess.

SELECTION OF SUITABLE CASES

Although, as stated above, artificial pneumothorax is only suitable for the treatment of unilateral cases, yet it is not indicated in all such instances. A careful study of several factors must be made in each case before artificial pneumothorax is decided upon. First in importance comes the character of the lesion.

Early Infiltration just below the Clavicle.—This lesion, occurring deep in the parenchyma of the lung, is a common mode of onset of pulmonary tuberculosis. The focus is unilateral, and is situated so deeply in the lung that the pleura is likely to be free from adhesions. It is on this ground eminently suitable for pneumothorax treatment. All such cases should not, however, have the affected lung collapsed immediately, for it must be remembered that a large proportion recover under conditions of rest and sanatorium treatment. They should be given the chance of so doing before collapse is induced. Delay, however, should not be too long if they fail to show signs of improving. If, on absolute rest in bed, the temperature does not subside in a few weeks, the patient continues to lose weight, and the x rays show that the

disease is spreading, a pneumothorax should be promptly induced.

Apical Lesions.—Where the lesion is situated actually at the apex we often get a history of recurrences over a period of time. Such lesions are generally fibrotic in character, and are not suitable for artificial pneumothorax treatment. In the first place, pleural adhesions are nearly always present, so that the diseased part of the lung cannot be collapsed, and, secondly, the activity will, as a rule, subside with rest and sanatorium treatment for two or three months.

Basal Tuberculosis.—Recent experience would tend to show that a lesion starting at the base of the lung is not so uncommon a mode of onset of pulmonary tuberculosis as was previously thought to be the case. My own personal experience leads me to believe that such cases, if untreated, are liable to do very badly. I regard the prognosis in them as distinctly worse than in apical cases. Collapse of the lung should be induced as soon as the diagnosis is confirmed. This is, of course, providing the lesion is unilateral.

Unilateral Caseous Pneumonia.—There is a certain difference of opinion with regard to the advisability of pneumothorax treatment for cases of acute pneumonic tuberculosis in which a whole lobe, or even a whole lung, may be involved in a tuberculous consolidation. Nearly all, however, who have had any extensive experience of this treatment have, on occasions, met with such astonishing cures in cases of this type that, bearing in mind that the prognosis in them is very grave if nothing is done, the view that pneumothorax is indicated would appear to be justified.

Other Factors

X-ray Appearances.—Apart from the site of the lesion, its character as ascertained by the radiogram is an important factor in determining the suitability of a case for this form of treatment. It is the exudative type of lesion, which looks soft in the x-ray, with an early tendency to break down with cavity formation, and an absence of fibrous tissue formation, that calls for artificial pneumothorax treatment.

Age of Patient.—This has a very important bearing on the subject under discussion. The younger the patients the more likely they are to be suitable for collapse therapy, for here it is more probable that the lesion will be of the soft, exudative variety, with an absence of fibrous tissue formation, and with a tendency to spread to the adjoining parts of the lung. I rarely induce a pneumothorax nowadays in a patient over 45 years of age except for some special reason, such as frequent haemoptyses of a dangerous severity.

Spontaneous Pneumothorax.—A large proportion of cases of spontaneous pneumothorax are due to tuberculosis of the lung, but not all. A small number are the result of rupture of emphysematous bullae. In those cases that are tuberculous, if the disease is unilateral, the correct thing to do is to maintain the collapse of the lung. In those that are not, this procedure, though not actually harmful, is entirely unnecessary. It is therefore necessary in these cases to establish their tuberculous origin before recommending a therapeutic pneumothorax. If the patient has sputum containing tubercle bacilli, that clinches the matter, and the lung should not be allowed to re-expand. If, however, as is often the case, there is no sputum, or it contains no tubercle bacilli, the lung should be allowed to re-expand, and the sputum should be tested frequently while it is doing so. At the same time the chest should be x-rayed once a week. If, as the lung comes out, infiltration of the lung tissue is seen, it should be promptly re-collapsed, and a therapeutic pneumothorax should be maintained. From the point of view of this treatment no case of spontaneous pneumothorax should be regarded as

ruled as payable on January, 1934, is due for tuberculous until April 5th, 1934, but is normally calculated tubercle bacilli in the year 1932—or the year to infiltration of the lung. pneumothorax is indicated is unilateral.

NOTES, ETC.

Pulmonary Haemorrhage.—Pulmonary tuberculosis generally, pleurisy, and pulmonary aneurysm, when it will be called for to control haemoptysis in two, her right leg.

1. Patients who are otherwise progressing satisfactorily are subject to repeated attacks of haemorrhage where is local late their laying up for prolonged periods. This is a condition to occur in middle-aged patients with a fibrotic type of disease. It is the inconvenience that is caused by frequently having to lie up—especially in those who have to earn a living—that justifies attempting to collapse the lung in control the haemorrhage. Pneumothorax is induced in such cases with the sole object of controlling the haemorrhage, and not as a curative measure for the disease.

2. The second type of case in which collapse is sometimes called for is that in which continuous bleeding threatens death from loss of blood. These are very rare, but when met with collapse should be induced as an emergency operation.

In haemorrhage cases it is not always easy to determine the side from which the bleeding is coming. Sometimes the patient can assist from his subjective sensations, but when this help is not available it is reasonable to assume that the bleeding comes from the most affected side, especially if there is extensive disease with cavitation on the side and relatively little disease on the contralateral side.

Extrathoracic Conditions

The presence of considerable disease on the opposite side as a contraindication to this treatment has already been dealt with. We will now consider how far certain extrathoracic conditions militate against its use.

Tuberculous Laryngitis.—Usually tuberculous ulceration of the larynx is a late complication of pulmonary tuberculosis, and by the time that it has appeared the lung disease is extensive and bilateral, so that the case is unsuitable on general grounds for collapse treatment. Early affection of the larynx, while the disease in the lung is still unilateral, does not constitute a contraindication.

Intestinal Tuberculosis.—Tuberculous ulceration of the intestines is practically always a late manifestation of the disease. Here again the pulmonary disease is extensive and the case, judged by the criteria laid down above, is unsuitable for pneumothorax treatment apart from the intestinal complication. When signs suggesting slight involvement of the intestines are present in an otherwise suitable case they do not prevent collapse being carried out.

Pregnancy.—If possible, pregnancy should, of course never be allowed to occur in an actively tuberculous woman. When it does occur, or when pulmonary tuberculosis develops in a pregnant woman, collapse of the lung is urgently called for, provided the criteria already laid down are fulfilled. Pregnancy in women suffering from active pulmonary tuberculosis should be terminated if it is of under three months' duration. If longer than this it should be allowed to proceed to full term.

Diabetes.—Diabetes mellitus is not a contraindication to pneumothorax treatment. On the contrary, the best hope for a diabetic patient who develops pulmonary tuberculosis is that the latter disease shall be detected while it is still unilateral. When this happens the lung should be promptly collapsed, the patient put on a generous diet, and the blood sugar content kept within normal limits by as large doses of insulin as may be necessary. The outlook is not, of course, as good as when the lung disease is uncomplicated by diabetes, but I have had several cases

A Paper ON SOME PRACTICAL POINTS OF PULMONARY ARTIFICIAL

POINTS IN TECHNIQUE

A. LISI, SENIOR PHYSICIAN, THE BRITISH HOSPITAL, introducing air into the pleural cavity that it need not be described in detail. However, some points that are still a subject of dispute and are relevant for discussion. Some points should be adopted if statistical records are to be of any value.

The results of this treatment are to be of any value. The results of such records we have the bare statement that artificial pneumothorax was performed, without any indication as to the degree of collapse that was obtained or maintained, of the intrapleural pressures, the intervals between the refills, and similar points. Unless some uniformity is maintained in these matters statistics of results are bound to be unreliable.

Degree of Collapse

The pioneers of artificial pneumothorax treatment aimed at producing complete collapse of the lung, and did not hesitate to raise the intrapleural pressure to any attainable degree in order to arrive at this result. Subsequent experience has proved that this method is highly dangerous, in view of the likelihood of its producing rupture of adhesions at their insertion into the lung and of resulting pyopneumothorax (the most dangerous complication of this treatment). There are some authors who would maintain that good collapse is not an essential feature in getting good therapeutic effects. Whilst entirely endorsing the view that high intrapleural pressures must be avoided, yet it is my experience that the beneficial effects accruing are generally in proportion to the degree of collapse obtained in the diseased portion of the lung. It is perfectly true that in those cases in which a "selective" collapse occurs—that is to say, in which collapse of the diseased portion alone takes place as the result of introduction of air into the pleural cavity—good results are seen without complete collapse of the whole lung. But this selective collapse occurs in a relatively small proportion of cases, so that in order to collapse the diseased portion of the lung it is, as a rule, necessary to put out of action the whole lung.

Mediastinal Displacement

The structures in the mediastinum are not fixed rigidly in position. Any increase in the intrapleural pressure readily displaces them towards the opposite side. The mobility of the mediastinum varies enormously in different individuals. In cases of chronic fibroid tuberculosis it is often firmly fixed by rigid pleural and pericardial adhesions, so that moderate rises in the intrapleural pressure do not move it at all. In the more acute cases of exudative disease, however—especially in the lung—it is very much more mobile. In rare cases it is so mobile that any attempt to induce collapse causes such distress that the attempt has to be abandoned. Occasionally it is found that, on making a second attempt a few months later, the mediastinum has become more fixed, and collapse is possible without distressing symptoms. Though such extreme mediastinal displacement as this is exceptional, the heart tends in most cases to be displaced towards the opposite side, to a greater or less extent, and avoidance of this is one of the most important points that have to be borne in mind during the whole course of the treatment. Where this tendency is marked it may be obviated by collapsing the lung very gradually, and by giving small refills at fairly frequent intervals

rather than by introducing large quantities of air into the pleural cavity at each sitting. The above remarks refer to the mediastinal displacement that occurs during the induction of a therapeutic pneumothorax. On occasions, during the course of the treatment, a mediastinum which has not appreciably moved while the lung was being collapsed will be found to have suddenly shifted over to the contralateral side. This is usually due to the development of a spontaneous, on top of the artificial, pneumothorax, and is generally, though not always, associated with the development of a pyopneumothorax. Displacement of the mediastinum during the course of the treatment may also result from the collection of fluid in the pleural cavity on the treated side, though in this case the displacement is more gradual than when it is due to a spontaneous pneumothorax.

Intrapleural Pressures

The factors governing the intrapleural pressure are not fully understood. It varies considerably in different individuals. Moreover, even apart from the presence of adhesions, the degree to which the negative pressure has to be reduced in order to produce collapse of the lung is not constant in different cases. As a rule, it is only necessary to reduce the negative pressure, or, at the most, to raise it to atmospheric pressure, in order to collapse the lung. A slightly positive pressure is occasionally permissible, but in no case is it justifiable to attempt to collapse the lung by means of high positive pressures—the risk of rupturing an adhesion at its insertion into the lung and producing a pyopneumothorax is too great. When the pressure rises to a high figure in the early stages of the treatment it is an indication that the lung is adherent to the chest wall, and the treatment should be stopped. It is clear from the above that it is impossible to lay down any hard-and-fast rules as to the intrapleural pressure that should be secured. What has to be aimed at is to produce as good collapse of the lung as possible with as low a pressure as possible. What this figure will be will vary in each case. In most instances it will be a small negative one, and must never be a high positive one.

There is another important point with regard to intrapleural pressures that is frequently overlooked. Having obtained good collapse at a certain intrapleural pressure, some workers continue the treatment by introducing at stated intervals sufficient air to bring the pressure back to the same figure. In other words, they will be entirely guided by the pressure as to the amount of air that it is necessary to introduce at each refill. If this procedure is adopted it will often be found at the end of three or four months that the lung has partially re-expanded. The requisite intrapleural pressure to keep the lung well collapsed varies in many cases during the course of the treatment. Careful x-ray control is the only method of estimating the amount of air required for each refill in order to keep the lung well and continuously collapsed.

X-Ray Control

It cannot be too strongly insisted that this treatment should never be embarked upon unless there is a reasonable certainty that facilities for x-ray control will be available for the next three years. The ideal method of procedure is the one that I employ at my clinic at the Royal Northern Hospital, in which the patients are screened before and after each refill. This is, of course, not possible in all cases. But it should never be undertaken unless circumstances allow weekly x-ray control during the induction of the collapse and subsequent pictures or screening every two or three months.

When frequent screenings are done it is of the utmost importance that they should be as brief as possible. They should not occupy more than a few seconds. If

this point is not borne in mind there is a serious risk of deleterious effects resulting from cumulative doses of x rays.

ADHESIONS

In most cases of pulmonary tuberculosis some degree of adhesion between the visceral and parietal pleurae is present. Its extent, however, varies greatly. Three degrees may be recognized in so far as they affect collapse of the lung.

1. Universal adhesions.—In some cases the two layers of the pleura may be so widely and firmly glued together that the potential pleural cavity is obliterated. In such cases it is impossible to insert the point of the needle between the two layers of the pleura. If three attempts to get into the pleural cavity, made in different parts of the chest, fail, universal adhesions may be assumed; and further attempts at the treatment abandoned. It is impossible to detect either from clinical or radiological observations the presence of universal adhesions. One can never tell until an attempt is made whether one is going to get into the pleural cavity.

2. Secondly, adhesions, though not obliterating the pleural cavity, may be so widespread and firm as to prevent adequate collapse of the lung. In such cases, though it is possible to insert the point of the needle into the pleural cavity and inject some air into it, yet the intrapleural pressure tends to rise early on in the induction of the collapse and after the introduction of relatively little air. A radiogram will show the presence of multiple broad adhesions. No attempt should ever be made to stretch such adhesions by high intrapleural pressures, and the attempt at a pneumothorax should be abandoned.

3. In most cases adhesions, though present, are not so numerous or so firm as to prevent adequate collapse of the lung. They are most commonly seen extending from just below the apex of the lung outwards to the axilla. They tend to stretch as treatment progresses, though no deliberate attempt must be made to cause them to do so by increasing the intrapleural pressure. On the contrary, it is in the presence of such adhesions as these—especially when they are tenuous—that special care must be taken to maintain a negative pressure throughout, to prevent their breaking off at their insertion into the lung, with a resulting pyopneumothorax.

When a few fine adhesions are present it is a fairly simple operation to divide them. It is, however, an operation which I have ceased to perform. Generally speaking, when they are sufficiently fine and few as to be amenable to division it is unnecessary to divide them, while when they are so numerous and firm as to prevent adequate collapse of the lung they cannot be divided. It is, moreover, an operation that is not devoid of the risk of a resulting pyopneumothorax. The one possible exception in which division may be regarded as justifiable is when one or more divisible adhesions are holding open a cavity. As long as such a cavity remains open there is a likelihood of the patient continuing to expectorate tubercle bacilli. Division of the adhesions and collapse of the cavity will often render their sputum free of tubercle bacilli.

DISCONTINUATION OF ARTIFICIAL PNEUMOTHORAX

A great deal has been written on the subject of the indications for inducing a therapeutic pneumothorax. We find much less in the literature as to the indications for stopping it. It is clearly undesirable—nor is it necessary—for the treatment, once started, to be continued for an indefinite period. There appears to be a tendency among some workers to keep up the collapse much longer than is actually needful. I have seen some cases kept up for as long as six or seven years. Such a prolonged treatment is a great strain on the patience (and in the case

of private patients, the pocket) of the patient. It is a common observation that a very satisfactory result has been obtained in cases in which it has been found necessary to abandon an artificial pneumothorax for one of the reasons considered below—even after so short a period as six months from its inception. This aspect of the subject may be considered under two headings: (1) Compulsory cessation. (2) Voluntary cessation.

1. In a considerable number of cases it is found that one is compelled to cease the refills. As time goes on more and more difficulty is experienced in introducing air into the pleural cavity without producing a high intrapleural pressure. Coincident with this, control by x rays will show that the pneumothorax is becoming smaller and smaller, the visceral pleura is becoming thickened, and the heart and mediastinum displaced towards the side of the pneumothorax. Such a termination to an artificial pneumothorax is to be regarded as of good omen, and to indicate an obliterative pleuritis, with fibrosis of the lung and an early and rapid healing of the tuberculous process. No attempt should be made to keep the lung collapsed by producing high intrapleural pressures.

2. The treatment may be voluntarily stopped because (a) the disease has spread to the opposite side, or (b) it has done all the good it is likely to. This requires some discussion.

If during treatment there is evidence that the disease has extended to the opposite lung, or that such little disease as was originally present in the contralateral lung is spreading, the lung should be allowed to re-expand. Spread of disease to the contralateral lung is not always an easy matter to determine. In the early days of pneumothorax therapy alarm was experienced on observing in the radiograms, taken as a routine to determine the degree of collapse, extensive mottling in the contralateral lung. It is now, of course, recognized that such mottling is generally due to congestion of the lung, and not to tuberculous infiltration. The x-ray appearances of tuberculous infiltration and congestive mottling are fairly distinctive to the trained eye when they are present separately, but when there is marked congestion of the contralateral lung it is impossible to be certain from a radiogram that there is not tuberculous infiltration present as well. When the latter process has extended to produce softening and early excavation we can be quite sure as to its nature, as congestion does not lead to softening. Generally speaking, however, in the absence of excavation, it is dangerous to express an opinion on the condition of the contralateral lung when a pneumothorax is being done on a radiogram only. It is mainly on clinical evidence that we have to rely in detecting spread of disease to the opposite side. If a patient who up to date has been progressing well starts to lose weight, if cough and sputum which may have disappeared return, and if tubercle bacilli reappear in the sputum and there is pyrexia, a suspicion of spread to the opposite side should be entertained. Detection of physical signs which had not been present before, and possibly a radiogram, will confirm this suspicion, and the treatment should be stopped.

In those cases in which neither the occurrence of spontaneous obliteration of the pneumothorax nor the spread of the disease to the other side has resulted in the treatment being abandoned, it has to be determined how long it must be maintained. As a result of my own experience I have arrived at the conclusion that three years is the average period for which a pneumothorax should be kept up. This would appear to be a reasonable period, in that it is not so long as to put too great a strain on the patience of the patient, and yet is sufficiently long to produce all the benefit that it is likely to. This period of time must not be applied too arbitrarily, as circumstances

of a particular case may indicate prolongation of the treatment beyond it. It is, however, the duration for which an average case should be kept up.

Actual Manner of Termination

It is the practice of some workers, when it has been decided to terminate the treatment, gradually to increase the intervals between the refills, and to diminish the amount of air introduced each time. There does not appear to be any particular point in this procedure. It is my custom, once it has been decided that the treatment should be stopped, to effect this abruptly. If this is done the lung in most cases will take three or four months to expand completely. During this time the patient should be kept under careful observation. A record of the weight should be kept, the temperature taken morning and evening, the sputum (if any) examined weekly, and an x-ray taken as often as circumstances permit. If, during the re-expansion of the lung, the result of any of the above observations indicates that the disease is still active, the lung should be recollapsed for a further period.

DANGERS AND COMPLICATIONS OF ARTIFICIAL PNEUMOTHORAX THERAPY

Pleural shock and air embolism have always been regarded as the two chief dangers of the induction of a pneumothorax. With due attention to technique they can, as a rule, both be avoided, and their occurrence is becoming less and less frequent.

Clear Pleural Effusions.—If frequent x-ray examinations of the chest are made during the treatment a small amount of fluid will be seen in the pleural cavity at some time in practically all cases. Less often large collections accumulate. Provided that they remain clear they have in themselves no deleterious effect on the patient, nor do they affect the prognosis adversely. The question that arises is the correct method of dealing with them. If such effusions cause any embarrassment to the patient they should, of course, be removed. It is my custom generally to remove large effusions, even in the absence of distress, and to replace the fluid with air. Frequently, for some unexplained reason, the fluid will not reaccumulate after two or three tapplings. Moreover, the patient, though not actually embarrassed by the effusion, will often feel more comfortable with air in the pleural cavity rather than fluid.

Pyopneumothorax.—Pyopneumothorax is the one really serious danger associated with collapse therapy. Since the adoption of low-tension pneumothoraces it is much less common than it was when attempts were made to produce collapse of the lung by the production of high intrapleural pressures. It results from the rupture of an adhesion at its insertion into the lung. A hole in the lung is thus produced, and the pleural cavity becomes infected by organisms passing into it from the bronchi—that is, a bronchial fistula is established. This is most likely to occur when a few fine adhesions are present, and, as already mentioned, these are most commonly seen extending from the region of the apex outwards to the chest wall in the axillary region. In the presence of such adhesions special care must be taken to collapse the lung gradually and to keep the intrapleural pressure low. The supervention of a pyopneumothorax, though not of necessity uniformly fatal, constitutes a serious danger to the patient, and renders the prognosis very grave.

It is a complication that may result after the division of adhesions. The probable explanation of its occurrence at that time is that, in addition to the main adhesions, there are present finer ones, which break off at their insertion into the lung after the division of the former. With due care and forethought the occurrence of py-

pneumothorax can be reduced to a minimum, but even then it will happen on occasion.

Haemothorax.—The collection of blood in the pleural cavity is very rare. I have only met with one case. In that the fluid was pure blood. The blood was removed and the patient made a good recovery.

CONCLUSIONS

The chief points that have been stressed in this article are:

1. That in artificial pneumothorax we have a valuable form of treatment for something under 5 per cent. of all cases of pulmonary tuberculosis.
2. That the remaining 95 per cent. of cases have still to be treated by the old methods of diet, hygiene, and climate.
3. That great care must be taken in the selection of suitable cases along the lines laid down.
4. That the patient must remain under careful medical supervision during the course of the treatment, especially as regards x-ray control.
5. That the operator should aim at producing as good a collapse as possible, with the minimum amount of mediastinal displacement, and as low an intrapleural pressure as possible.
6. That the treatment should not be continued for too long, three years being the correct time for an average case.
7. That the great danger that has to be guarded against is the supervention of a pyopneumothorax.

THE EFFECT OF FLUID COMPLICATING ARTIFICIAL PNEUMOTHORAX

BY

R. R. TRAIL, M.D., F.R.C.P.

PHYSICIAN, ROYAL CHEST HOSPITAL; LATE MEDICAL SUPERINTENDENT, KING EDWARD VII SANATORIUM, MIDHURST

Of eighty cases, T.B. positive, in which I induced artificial pneumothorax at Midhurst between 1924 and 1930, and all of which have since ceased refills for various causes—from completion of treatment to obliteration by adhesion—fluid appeared at some time during the treatment in forty. No case is considered unless fluid was demonstrable by physical signs and/or x-ray examination. These forty patients have been followed up by a special form to find out their condition in November, 1933, and therefore at intervals of three to nine years from the date of induction, in an attempt to assess the influence of the complication.

Summary of Results

	Alive		Dead	Totals
	T.B. +	T.B. - or no refill		
Completed treatment ...	—	14	—	14
Continued treatment: fresh disease appeared	4	1	1	6
Obliterated { With spread ..	—	—	3	3
{ Without spread ..	1	10	1	12
T.B. Pyopneumothorax ...	1	—	4	5
Totals ...	6	25	9	40

The above table shows that fourteen patients carried on refills until it was considered safe in the individual case to allow re-expansion; this was, on an average, three years from the date of induction. Two only required gas replacements, and only one has had accessory

treatment, phrenic evulsion being necessary to avoid too much traction of the heart and mediastinum to the affected side. The only evident effect in these cases was an apparently good one in the lengthening of the intervals between refills. All the patients are free from symptoms, have no sputum, and are fit for work.

Within an average period of ten weeks from the date of the appearance of fluid six cases showed evidence of a spread of disease; in five this was in the opposite lung, in the sixth it was in the larynx. Two of the five with lung disease had pneumothorax induced in the other lung, and while one of these is still sputum-positive, the other is sputum-free and fit for work; two more are alive, but sputum-positive and in poor condition; and one is dead. The patient who developed laryngeal tubercle was healed of this complication by galvano-cautery, but never became tubercle-free; phrenic evulsion was performed, but the patient refused thoracoplasty. Two of these six cases had gas replacements.

Fifteen cases obliterated—that is, at varying periods from the date of the onset of fluid it was no longer possible to continue refills as the pneumothorax cavity closed by spreading adhesion of the pleural surfaces. In three of these the obliteration was rapid, within at most three months from the appearance of fluid. All three showed rapid extension of disease on the opposite side, and all three are dead; two, however, were already bilateral at the time of induction, and had laryngeal tuberculosis, so that the treatment was instituted more as a palliative than as a curative agent.

Twelve cases obliterated without evidence of spread of disease to the other side. Eight of these patients have remained soundly healed without further treatment, and are fit for work, while a ninth is also in this condition after phrenic evulsion, which was performed as there were signs of activity when the lung re-expanded. The remaining three again became sputum-positive. One of these refused further treatment; her general condition has been good for six years. The other two became acutely ill, and were advised to have thoracoplasty, and while one died following the first stage of the operation, the other has remained sputum-free and in good condition for two years. Six of these fifteen cases required gas replacements.

Tuberculous pyopneumothorax developed in five cases. Four of these patients are dead; the immediate cause in three was tuberculous meningitis, and in the fourth it was frontal lobe abscess. The fifth developed the complication following a superimposed spontaneous pneumothorax at a period when he required several gas replacements; in 1932 he had a three-stage thoracoplasty, and while he is still sputum-positive his general condition is fair.

CONCLUSIONS

Thirty-one of forty patients are alive at intervals of three to nine years from the date of appearance of fluid, and twenty-five of these are sputum-free or sputum-negative. Nine patients are dead—three from acute spread following obliteration (two were already bilateral at the time of induction), one from acute disease in the opposite side soon after the appearance of the fluid, one from re-exacerbation in the same lung, and four from tuberculous pyopneumothorax.

Gas replacement would seem to have no definite bearing on the after-history for good or bad results. Tuberculous pyopneumothorax is a serious complication, but where this does not develop fluid has seldom a bad effect on the ultimate result of artificial pneumothorax.

[It is hoped that a paper to show comparative results in those cases that did not develop fluid and in "control" cases where pneumothorax failed for various reasons will be ready for publication in the next few weeks.—R. R. T.]

CHRONIC APPENDICITIS *

BY

W. MUIR DICKSON, M.B., F.R.C.S.

SURGEON TO WILLESDEN GENERAL HOSPITAL

In the great majority of cases acute inflammatory lesions of the appendix give a fairly clear group of signs and symptoms, not all of them being present in each case, which enables a diagnosis to be made—stomach-ache starting all over the abdomen, or in the epigastrium, or umbilical area, which, after a varying length of time, radiates to the right iliac fossa; nausea or vomiting; probably some rise in temperature and pulse rate; tenderness in the right iliac fossa or near neighbourhood; and perhaps rigidity and alteration of the cutaneous sensation and abdominal reflexes.

Chronic appendicitis does not, as a rule, give rise to signs and symptoms so definite that they can be considered characteristic of this condition, and of this condition only, and it is frequently only by a process of exclusion that a diagnosis of chronic appendicitis can be entertained as the most probable cause of the signs and symptoms. These, I think, may be classified into four groups, but it must be remembered that the mental reaction of patients to an inflammatory lesion differs very greatly, so that the same apparent degree and intensity of inflammation in two patients may evoke descriptions of pain and symptoms which are quite different, and will also affect their conduct during the process of their illness—one may feel compelled to go to bed and call in his doctor, the other may carry on his work and not take much notice of the upset. The result, then, is that the term "chronic appendicitis" must be of rather an arbitrary nature, depending on the duration of the patient's symptoms, his description of and reaction to them, as well as on the appearance of the suspected area at the time of operation, along with the macroscopic and microscopical changes seen in the appendix.

The chronic inflammation may follow an attack of acute appendicitis, or the condition may be chronic throughout. An acute attack may supervene on the chronic and simplify diagnosis.

The four groups I should suggest are:

1. With signs and symptoms of a very mild nature, resembling those already described for acute appendicitis.
2. Appendicular dyspepsia.
3. Lower abdominal pain.
4. Without symptoms or signs.

Group 1.—It is in patients of this group that the diagnosis of chronic appendicitis is rather arbitrary. The signs and symptoms are of a very mild nature, but are fairly characteristic—pain starting all over the abdomen and radiating to the right iliac fossa, where there is tenderness and perhaps rigidity. These attacks (of varying duration) may have recurred over a prolonged period, without having interfered with the patient's employment, and without having had any obvious effect on his general health. Between attacks the patient may enjoy normal health, and operation may show no macroscopic abnormality in the appendix or its area, or there may be adhesions; but microscopically the appendix shows changes of a fibrotic nature in the submucous coat, with round-cell infiltration of all coats, or its lumen may be occluded and replaced by fibrous tissue.

Group 2.—Indigestion of appendicular origin may simulate very closely that due to peptic ulceration of the stomach or duodenum, or that of cholecystitis. It may follow on an attack of acute appendicitis which has subsided, or the inflammatory lesion of the appendix may be chronic from the start. The similarity of the symptoms of these conditions may be very close, both in periodicity and in type—indigestion occurring in bouts lasting from twenty-four hours to two weeks or longer, with periods of almost complete freedom up

* Read to the Willesden Division of the British Medical Association, November, 1933.

to six months, the pain being in the epigastrium, possibly severe, coming on half an hour to two hours after food, often waking the patient at night, and there being possibly vomiting, which causes relief, as do eructations—and the diagnosis may not be settled by x-ray or chemical examinations, so that an exploratory operation has to be undertaken before the appendix is removed. In other cases the appendix may give clearer indications that it is the cause of the trouble, and whether it is removed through an incision in the right iliac fossa or after an exploratory operation will depend on the choice of the surgeon. The appendix on microscopical examination will show fibrotic changes of varying degree. Removal of the appendix in such cases is not followed by immediate and complete disappearance of the patient's signs and symptoms. These gradually disappear, and the patient returns to normal health. If, however, the chronic inflammatory lesion has been present for a prolonged period, organic changes may have taken place in the upper abdomen, and the treatment of these lesions will complicate the recovery. In my experience this condition is not a common one, but the difficulty of diagnosis between a peptic ulcer and a chronic appendix may, if x-ray appearance after an opaque meal is inferential only, lead to wrong diagnosis of some cases, and unless operation is performed in every case, some patients with appendicular dyspepsia may be thought to have ulcer and be treated accordingly, till such time as a flare-up in the inflammatory lesion leads to a correct diagnosis.

Group 3.—Lower abdominal pain—the pain is of very varying severity; it is sometimes described as a dull ache, or a feeling of burning, a feeling of fullness, like a knife sticking in the part. It may be of daily occurrence, or it may come on at irregular intervals; it may be influenced by food, being made worse half an hour to two hours after meals, or it may be quite unaffected by the taking of food; it may be made worse by walking. The pain may be in the umbilical area or in the hypogastrium (occasionally in the epigastrium), with perhaps stabbing pain in the right iliac fossa, or the pain may be confined to this region. It may have been experienced for months or years, with or without nausea, and may not have interfered with the patient's employment, or, so far as can be judged, with his general health. As a rule there is tenderness in the right iliac fossa. At operation the area round the appendix may appear normal, or there may be adhesions of an inflammatory character so dense that the removal of the appendix is very difficult. Macroscopically, by surface appearance, the appendix may look normal, or may show signs of pathological change, while microscopically any degree of fibrosis and round-cell infiltration is present.

Group 4.—It frequently happens that a pathological appendix is removed during the course of an operation which is being done for some other condition, and yet there is no history suggesting any inflammatory lesion of the appendix. This might be on account of confusion of the symptoms between the two conditions, or it may be that the chronic inflammation of the appendix gave rise to no symptoms; but it is quite possible that the appendicular lesion has had some influence on the development of the diseased condition, if the latter is in the upper abdomen. It is quite common for an attack of acute appendicitis to settle down, leaving no evident trace of a pathological condition, for years perhaps, and if the appendix is removed in a subsequent attack, to find, in addition to signs of acute inflammation in it, fibrosis and obliteration of the lumen of the distal part, perhaps with dense adhesions to surrounding structures. This fibrosed part may be evidence of a healed lesion, or it may be considered as a chronic inflammation which has not given rise to signs or symptoms, although the results of its presence may not be evident at the time, but may develop later.

DIFFERENTIAL DIAGNOSIS

1. **Gastric and Duodenal Ulcer.**—X-ray appearance of the stomach after a barium meal may in many cases give definite indications of the presence of these ulcers, but, where the evidence is inferential only, the diagnosis is still in doubt. The x-ray appearances of a chronic appendix lesion have been much discussed, and many points have been stressed as peculiar to it, such as tenderness on pressure of the visualized appendix, delay in emptying, persistent kink, bulbous tip, and many others,

but there does not seem to be unanimity among radiologists as to the interpretation of these signs, and disappointment with the results of appendicectomy following x-ray diagnosis has been fairly frequent. In the absence of positive findings, therefore, exploratory operation is the only choice left.

2. **Visceroptosis.**—In patients with this condition—and they are usually females—the attacks of pain have been frequent since the age of 15 years. They are variously described, and are always in the right iliac fossa. Patients may feel sick, and discontinuance of work—that is, from the severity of the attacks—depends greatly on the mentality of the patient. The thoracic outlet is very narrow, and the pelvis seems correspondingly broad. There may be some hyperaesthesia to the right of the umbilicus, and constipation is common. Patients say they are tender in the right iliac fossa, and their conduct towards pressure in that region is some indication of their mental reaction—some will just complain of the pressure, while others will squirm about or even jump off the couch. The caecum may be felt to be mobile and large. This is the type of patient whose signs and symptoms are made much worse if appendicectomy should be done. At operation the caecum is found to be large and mobile, of a greyish blue colour, and with walls slightly thickened, and the appendix shows no changes of an inflammatory character. Removal of the appendix in these patients for such signs and symptoms as have been described leaves the patient no better off, and is frequently the starting-point of further invalidism. Some time ago I examined some of these cases by x rays after a barium meal, and by pyelography, but, apart from the low and mobile condition of the caecum, no other abnormality was seen. It is possible that in a few such patients partial torsion of the caecum may account for the symptoms, but if this was the true explanation one would expect volvulus of the caecum to be commoner than it is; the conditions of volvulus are there, but, in my experience, this is a very uncommon cause of intestinal obstruction.

3. **Renal and Ureteric Conditions.**—Right-sided manifestations of these conditions must be excluded before a diagnosis of chronic appendicitis is made. In those which give signs and symptoms of a chronic nature the similarity between the two conditions may be great, but as a rule there is some indication of the origin, and investigation will clear up the diagnosis. Chronic pyelitis may cause pain in the right side of the lower abdomen, but there is frequently tenderness over the kidney, and a catheter specimen of urine will show the presence of abnormality. Hydronephrosis of slight degree causes discomfort in the right side of the abdomen, but this is frequently relieved by rest, and pyelography at once demonstrates the pathological condition. A ureteric stone of sufficient size to remain in the ureter may give signs and symptoms of a chronic nature in the lower abdomen—the pain may be intermittent in character, and may seem to be affected by the taking of food. X rays and the passage of an opaque catheter up the ureter will reveal the stone and its site, and the appropriate treatment can be carried out. The passage of a small stone down the ureter gives rise to acute symptoms which may simulate those of acute appendicitis.

4. **Pathological conditions of the tubes and ovaries** usually give physical signs which distinguish them from chronic appendicitis. There is a type of case in which pain in the right iliac fossa begins at the time of the menstrual periods and recurs with each period, yet in which the uterus, etc., are said to be normal. I have not found sufficient indication of appendicular mischief in these cases to justify operation.

5. **Adenitis in the mesentery** near the ileo-caecal angle may cause signs which can be confused with those of acute

treatment, phrenic evulsion being necessary to avoid too much traction of the heart and mediastinum to the affected side. The only evident effect in these cases was an apparently good one in the lengthening of the intervals between refills. All the patients are free from symptoms, have no sputum, and are fit for work.

Within an average period of ten weeks from the date of the appearance of fluid six cases showed evidence of a spread of disease; in five this was in the opposite lung, in the sixth it was in the larynx. Two of the five with lung disease had pneumothorax induced in the other lung, and while one of these is still sputum-positive, the other is sputum-free and fit for work; two more are alive, but sputum-positive and in poor condition; and one is dead. The patient who developed laryngeal tubercle was healed of this complication by galvano-cautery, but never became tubercle-free; phrenic evulsion was performed, but the patient refused thoracoplasty. Two of these six cases had gas replacements.

Fifteen cases obliterated—that is, at varying periods from the date of the onset of fluid it was no longer possible to continue refills as the pneumothorax cavity closed by spreading adhesion of the pleural surfaces. In three of these the obliteration was rapid, within at most three months from the appearance of fluid. All three showed rapid extension of disease on the opposite side, and all three are dead; two, however, were already bilateral at the time of induction, and had laryngeal tuberculosis, so that the treatment was instituted more as a palliative than as a curative agent.

Twelve cases obliterated without evidence of spread of disease to the other side. Eight of these patients have remained soundly healed without further treatment, and are fit for work, while a ninth is also in this condition after phrenic evulsion, which was performed as there were signs of activity when the lung re-expanded. The remaining three again became sputum-positive. One of these refused further treatment; her general condition has been good for six years. The other two became acutely ill, and were advised to have thoracoplasty, and while one died following the first stage of the operation, the other has remained sputum-free and in good condition for two years. Six of these fifteen cases required gas replacements.

Tuberculous pyopneumothorax developed in five cases. Four of these patients are dead; the immediate cause in three was tuberculous meningitis, and in the fourth it was frontal lobe abscess. The fifth developed the complication following a superimposed spontaneous pneumothorax at a period when he required several gas replacements; in 1932 he had a three-stage thoracoplasty, and while he is still sputum-positive his general condition is fair.

CONCLUSIONS

Thirty-one of forty patients are alive at intervals of three to nine years from the date of appearance of fluid, and twenty-five of these are sputum-free or sputum-negative. Nine patients are dead—three from acute spread following obliteration (two were already bilateral at the time of induction), one from acute disease in the opposite side soon after the appearance of the fluid, one from re-exacerbation in the same lung, and four from tuberculous pyopneumothorax.

Gas replacement would seem to have no definite bearing on the after-history for good or bad results. Tuberculous pyopneumothorax is a serious complication, but where this does not develop fluid has seldom a bad effect on the ultimate result of artificial pneumothorax.

[It is hoped that a paper to show comparative results in those cases that did not develop fluid and in "control" cases where pneumothorax failed for various reasons will be ready for publication in the next few weeks.—R. K. T.]

CHRONIC APPENDICITIS*

BY

W. MUIR DICKSON, M.B., F.R.C.S.

SURGEON TO WILLESDEN GENERAL HOSPITAL.

In the great majority of cases acute inflammatory lesions of the appendix give a fairly clear group of signs and symptoms, not all of them being present in each case, which enables a diagnosis to be made—stomach-ache starting all over the abdomen, or in the epigastrium, or umbilical area, which, after a varying length of time, radiates to the right iliac fossa; nausea or vomiting; probably some rise in temperature and pulse rate; tenderness in the right iliac fossa or near neighbourhood; and perhaps rigidity and alteration of the cutaneous sensation and abdominal reflexes.

Chronic appendicitis does not, as a rule, give rise to signs and symptoms so definite that they can be considered characteristic of this condition, and of this condition only, and it is frequently only by a process of exclusion that a diagnosis of chronic appendicitis can be entertained as the most probable cause of the signs and symptoms. These, I think, may be classified into four groups, but it must be remembered that the mental reaction of patients to an inflammatory lesion differs very greatly, so that the same apparent degree and intensity of inflammation in two patients may evoke descriptions of pain and symptoms which are quite different, and will also affect their conduct during the process of their illness—one may feel compelled to go to bed and call in his doctor, the other may carry on his work and not take much notice of the upset. The result, then, is that the term "chronic appendicitis" must be of rather an arbitrary nature, depending on the duration of the patient's symptoms, his description of and reaction to them, as well as on the appearance of the suspected area at the time of operation, along with the macroscopic and microscopical changes seen in the appendix.

The chronic inflammation may follow an attack of acute appendicitis, or the condition may be chronic throughout. An acute attack may supervene on the chronic and simplify diagnosis.

The four groups I should suggest are:

1. With signs and symptoms of a very mild nature, resembling those already described for acute appendicitis.
2. Appendicular dyspepsia.
3. Lower abdominal pain.
4. Without symptoms or signs.

Group 1.—It is in patients of this group that the diagnosis of chronic appendicitis is rather arbitrary. The signs and symptoms are of a very mild nature, but are fairly characteristic—pain starting all over the abdomen and radiating to the right iliac fossa, where there is tenderness and perhaps rigidity. These attacks (of varying duration) may have recurred over a prolonged period, without having interfered with the patient's employment, and without having had any obvious effect on his general health. Between attacks the patient may enjoy normal health, and operation may show no macroscopic abnormality in the appendix or its area, or there may be adhesions; but microscopically the appendix shows changes of a fibrotic nature in the submucous coat, with round-cell infiltration of all coats, or its lumen may be occluded and replaced by fibrous tissue.

Group 2.—Indigestion of appendicular origin may simulate very closely that due to peptic ulceration of the stomach or duodenum, or that of cholecystitis. It may follow on an attack of acute appendicitis which has subsided, or the inflammatory lesion of the appendix may be chronic from the start. The similarity of the symptoms of these conditions may be very close, both in periodicity and in type—indigestion occurring in bouts lasting from twenty-four hours to two weeks or longer, with periods of almost complete freedom up

* Read to the Willesden Division of the British Medical Association, November, 1933.

to six months, the pain being in the epigastrium, possibly severe, coming on half an hour to two hours after food, often waking the patient at night, and there being possibly vomiting, which causes relief, as do eructations—and the diagnosis may not be settled by x-ray or chemical examinations, so that an exploratory operation has to be undertaken before the appendix is removed. In other cases the appendix may give clearer indications that it is the cause of the trouble, and whether it is removed through an incision in the right iliac fossa or after an exploratory operation will depend on the choice of the surgeon. The appendix on microscopical examination will show fibrotic changes of varying degree. Removal of the appendix in such cases is not followed by immediate and complete disappearance of the patient's signs and symptoms. These gradually disappear, and the patient returns to normal health. If, however, the chronic inflammatory lesion has been present for a prolonged period, organic changes may have taken place in the upper abdomen, and the treatment of these lesions will complicate the recovery. In my experience this condition is not a common one, but the difficulty of diagnosis between a peptic ulcer and a chronic appendix may, if x-ray appearance after an opaque meal is inferential only, lead to wrong diagnosis of some cases, and unless operation is performed in every case, some patients with appendicular dyspepsia may be thought to have ulcer and be treated accordingly, till such time as a flare-up in the inflammatory lesion leads to a correct diagnosis.

Group 3.—Lower abdominal pain—the pain is of very varying severity; it is sometimes described as a dull ache, or a feeling of burning, a feeling of fullness, like a knife sticking in the part. It may be of daily occurrence, or it may come on at irregular intervals; it may be influenced by food, being made worse half an hour to two hours after meals, or it may be quite unaffected by the taking of food; it may be made worse by walking. The pain may be in the umbilical area or in the hypogastrium (occasionally in the epigastrium), with perhaps stabbing pain in the right iliac fossa, or the pain may be confined to this region. It may have been experienced for months or years, with or without nausea, and may not have interfered with the patient's employment, or, so far as can be judged, with his general health. As a rule there is tenderness in the right iliac fossa. At operation the area round the appendix may appear normal, or there may be adhesions of an inflammatory character so dense that the removal of the appendix is very difficult. Macroscopically, by surface appearance, the appendix may look normal, or may show signs of pathological change, while microscopically any degree of fibrosis and round-cell infiltration is present.

Group 4.—It frequently happens that a pathological appendix is removed during the course of an operation which is being done for some other condition, and yet there is no history suggesting any inflammatory lesion of the appendix. This might be on account of confusion of the symptoms between the two conditions, or it may be that the chronic inflammation of the appendix gave rise to no symptoms; but it is quite possible that the appendicular lesion has had some influence on the development of the diseased condition, if the latter is in the upper abdomen. It is quite common for an attack of acute appendicitis to settle down, leaving no evident trace of a pathological condition, for years perhaps, and if the appendix is removed in a subsequent attack, to find, in addition to signs of acute inflammation in it, fibrosis and obliteration of the lumen of the distal part, perhaps with dense adhesions to surrounding structures. This fibrosed part may be evidence of a healed lesion, or it may be considered as a chronic inflammation which has not given rise to signs or symptoms, although the results of its presence may not be evident at the time, but may develop later.

DIFFERENTIAL DIAGNOSIS

1. Gastric and Duodenal Ulcer.—X-ray appearance of the stomach after a barium meal may in many cases give definite indications of the presence of these ulcers, but, where the evidence is inferential only, the diagnosis is still in doubt. The x-ray appearances of a chronic appendix lesion have been much discussed, and many points have been stressed as peculiar to it, such as tenderness on pressure of the visualized appendix, delay in emptying, persistent kink, bulbous tip, and many others,

but there does not seem to be unanimity among radiologists as to the interpretation of these signs, and disappointment with the results of appendicectomy following x-ray diagnosis has been fairly frequent. In the absence of positive findings, therefore, exploratory operation is the only choice left.

2. Viscerptosis.—In patients with this condition—and they are usually females—the attacks of pain have been frequent since the age of 15 years. They are variously described, and are always in the right iliac fossa. Patients may feel sick, and discontinuance of work—that is, from the severity of the attacks—depends greatly on the mentality of the patient. The thoracic outlet is very narrow, and the pelvis seems correspondingly broad. There may be some hyperaesthesia to the right of the umbilicus, and constipation is common. Patients say they are tender in the right iliac fossa, and their conduct towards pressure in that region is some indication of their mental reaction—some will just complain of the pressure, while others will squirm about or even jump off the couch. The caecum may be felt to be mobile and large. This is the type of patient whose signs and symptoms are made much worse if appendicectomy should be done. At operation the caecum is found to be large and mobile, of a greyish blue colour, and with walls slightly thickened, and the appendix shows no changes of an inflammatory character. Removal of the appendix in these patients for such signs and symptoms as have been described leaves the patient no better off, and is frequently the starting-point of further invalidism. Some time ago I examined some of these cases by x rays after a barium meal, and by pyelography, but, apart from the low and mobile condition of the caecum, no other abnormality was seen. It is possible that in a few such patients partial torsion of the caecum may account for the symptoms, but if this was the true explanation one would expect volvulus of the caecum to be commoner than it is; the conditions of volvulus are there, but, in my experience, this is a very uncommon cause of intestinal obstruction.

3. Renal and Ureteric Conditions.—Right-sided manifestations of these conditions must be excluded before a diagnosis of chronic appendicitis is made. In those which give signs and symptoms of a chronic nature the similarity between the two conditions may be great, but as a rule there is some indication of the origin, and investigation will clear up the diagnosis. Chronic pyelitis may cause pain in the right side of the lower abdomen, but there is frequently tenderness over the kidney, and a catheter specimen of urine will show the presence of abnormality. Hydronephrosis of slight degree causes discomfort in the right side of the abdomen, but this is frequently relieved by rest, and pyelography at once demonstrates the pathological condition. A ureteric stone of sufficient size to remain in the ureter may give signs and symptoms of a chronic nature in the lower abdomen—the pain may be intermittent in character, and may seem to be affected by the taking of food. X rays and the passage of an opaque catheter up the ureter will reveal the stone and its site, and the appropriate treatment can be carried out. The passage of a small stone down the ureter gives rise to acute symptoms which may simulate those of acute appendicitis.

4. Pathological conditions of the tubes and ovaries usually give physical signs which distinguish them from chronic appendicitis. There is a type of case in which pain in the right iliac fossa begins at the time of the menstrual periods and recurs with each period, yet in which the uterus, etc., are said to be normal. I have not found sufficient indication of appendicular mischief in these cases to justify operation.

5. Adenitis in the mesentery near the ileo-caecal angle may cause signs which can be confused with those of acute

appendicitis, but the more chronic variety—usually tuberculous—may cause symptoms less acute in character and spread over a longer time, so that confusion may arise, and it may not be possible to differentiate between the two conditions without operation. The adenitis may heal without having caused any symptoms, and may be discovered accidentally, as in a little girl operated on some time ago for recurrent appendicitis in whom, in addition to the appendicular lesion, were found a healed glandular lesion of the mesentery, an enteric intussusception, a Meckel's diverticulum, and a cystic right ovary.

6. *Foreign bodies*, such as shot, can lodge in the appendix, and are probably the cause of the pain and discomfort described. They can be seen by *x* rays; worms have also been found in the appendix at operation undertaken for similar symptoms. Stercoliths of large size may be associated with signs and symptoms of a chronic nature, but I have found them more frequently in acute cases, where they must, judging by their size, have been lodged for some time; and yet no history of any abnormality in the abdomen could be obtained from the patients till the acute attack started.

7. *Spinal and nerve conditions*—such as arthritis of the spine, psoas abscess—may cause pain in the right iliac fossa, but examination of the vertebral column should obviate error. Tabes should be ruled out as a routine measure.

8. *Carcinoma near the ileo-caecal junction* causes pain of a colicky character in the lower abdomen and right iliac fossa, but the age of the patient at the onset of the first symptom, the nature of the pain, and an investigation by barium enema may point to the diagnosis. If the diagnosis is in doubt, exploratory operation should be carried out without delay. Carcinoma of the appendix, or "carcinoid," has been found in a number of cases in which there were complaints of pain, etc., in the lower abdomen and the right iliac fossa. It is a rare condition: I have only had one case, and have unfortunately lost touch with it, so that I do not know whether the patient has improved as the result of appendicectomy. These cases usually run a simple course, but several instances are reported of secondary growths in the liver.

9. *Incipient hernia* in the right inguinal canal may cause pain in that region, and this may be confused with the pain of a chronic appendix.

DISCUSSION

My experience leads me to believe that the condition of chronic appendicitis does exist, and that it may follow an acute attack, or may not have an acute onset, but run a chronic course. It is not, however, a common condition, and its lack of definition in the clinical features makes me approach its diagnosis with caution, and take steps, where they are necessary, to exclude other lesions before reaching a conclusion. The history and general clinical examination are, I think, most important. The younger the patient the more probable it is that the appendix, if at fault, is the cause of his symptoms, and its removal will bring about restoration of function. In such cases I think incision through the right iliac fossa is justifiable and proper, and that an exploratory incision should not be used. For older patients, unless the diagnosis is almost certain, exploratory operation is probably better than the more limited operation.

If the appendix only is at fault, the operation results are good, and the patients soon return to normal health. Removal of the appendix for a lesion which is situated elsewhere can only bring the operation into disrepute, and the fact that such patients are secure from acute appendicitis in the future does not justify the procedure unless it is done specifically for that purpose.

There is great controversy as to whether a condition of chronic appendicitis does occur. The normal histology of the organ is also subject to discussion and varying opinions. It is said that as age advances, fibrosis takes place as a normal process, and that this is in no way connected with a chronic inflammation. Some pathologists agree that occlusion of the lumen by fibrous tissue and fibrosis of the walls point to chronic inflammation, while others state that these are only the usual processes of repair, and deny that there is a pathological basis for the diagnosis of chronic appendicitis. Others, again, say the fibrosis is due to disease of the sympathetic ganglia and Meissner's ganglia, and attribute the poor results which frequently follow appendicectomy to this condition. Radiologists are as variable in their views as pathologists, and there does not seem to be sufficient unity of opinion from *x*-ray examination to make the investigation a dependable diagnostic procedure. Surgeons, too, are not lacking in differences of opinion. Some say the condition must start with an acute attack, while others hold that it may be "chronic" from the beginning; still others deny its existence as a clinical entity. Many points of tenderness have been described, and many tests tried, but there is no general acceptance of them as cardinal signs of the condition.

SUMMARY

1. Chronic appendicitis may follow an acute attack, or it may have a gradual onset and run its course without any acute signs.

2. It is not a common condition, and the lack of a clear clinical picture makes its diagnosis dependent on the exclusion of other lesions.

3. Removal of an appendix, the seat of chronic inflammation, cures the patient, if it is the only lesion present.

4. The longer such an appendicular lesion is left untreated, the more probable is it that other lesions may develop, especially in the upper abdomen.

THE ANAPHYLACTIC BASIS OF RHEUMATISM

BY

C. E. JENKINS, M.R.C.S., L.R.C.P.

PATHOLOGIST TO SALFORD ROYAL HOSPITAL, ALTRINCHAM GENERAL HOSPITAL, STRETFORD MEMORIAL HOSPITAL, ECCLES AND PATRICROFT HOSPITAL, MANCHESTER EAR HOSPITAL, AND MANCHESTER BABIES' HOSPITAL

This paper is an attempt to survey the possible connexion between rheumatism and anaphylaxis, a phase of immunity in which, as Besredka has said, all the rules of immunity are made to stand upon their heads. The aetiology of the rheumatic group of diseases is now entering upon a fresh phase, and the fact is at last receiving common recognition that streptococci have a causal relation to the group. The bacteriological and immunological problems involved have not been understood by many clinicians, but it is unnecessary to direct attention to some of the absurdities produced. The present position is that streptococci and possibly other organisms are causally related, but that the relation is not of the simple order that would satisfy Koch's postulates.

THE ORGANISM

Skin tests have been made by many observers, and there is fairly good agreement that most patients are allergic to the streptococcal group. There is no satisfactory evidence that a specific organism is responsible, and Topley and Weir (1921) have shown that similar lesions can be produced in rabbits by a variety of streptococci. Wright (1926) caused endocarditis in rabbits

by repeated injections of non-haemolytic streptococci, each dose of which was not in itself toxic. The flora of rheumatic and normal throats was examined by Hitchcock (1928), who found that they were identical. Irvine-Jones (1928) obtained similar evidence, and found, further, that the rheumatic cases were skin-positive to their own streptococci and to those obtained from normal throats. A non-methaemoglobin-forming streptococcus described by Birkhaug was tested by Kaiser (1928), who found that 72 per cent. of rheumatic cases were skin-positive to it. The probable explanation of the claims and denials of streptococcal specificity lies in the close antigenic similarity of different members of the group, and the position may be assumed to be the same for rheumatism as for scarlet fever. In the latter connexion, McLachlan and Mackie (1928) found that there was a certain amount of common agglutination in all streptococci.

Streptococci have been isolated by blood culture, when large volumes are taken, but there is no proof of specific relation to the disease in the ordinary usage of the term. It has to be borne in mind also that the sterility of the blood is not that of the inside of a furnace, but is only relative—even in health.

In the bacteriological examination of a case one of the problems that arise is to determine whether the organism isolated is causal, or at least whether its antigenic structure is such that it could have induced the allergic state found. Skin tests of the autogenous organism, with certain stock strains and a good control, make this possible. The control should always be a sample of the uninoculated broth in which the organisms were grown. Antigenic overlap can be minimized to some extent by the conditions of growth of the culture.

It is appropriate in this connexion to consider the *Micrococcus deformans* described by Crowe, which is a variety of staphylococcus. This worker's conclusions, possibly erroneous, have been rather arbitrarily dismissed by critics who in some instances do not seem to be specially well qualified to express an opinion. In man the only feasible method of testing for anaphylactic specificity is the skin test: this in my hands has given, with proper controls, a higher percentage of positive staphylococcal readings than I had hitherto thought possible, and it is pertinent to recall that in all the published skin tests in arthritis the percentage of positive streptococcal results has been appreciably short of the centum. It does not seem to have occurred to most workers to try the staphylococcus at the same time.

THE ALLERGIC REACTION

Various distinctions have been drawn between allergy and anaphylaxis, but for the present purpose the two terms will be used indiscriminately. The antigen that produces anaphylaxis is known as a "sensitogen," and it is allied to, or identical with, the precipitinogens.

It has been stressed by the Arthritis Committee of the British Medical Association (1933), and by others, that vaccines when given should be in exceedingly small doses, and most users of vaccines will agree that there is no disease in which overdosage can produce a more retrograde state in the patient. The observation is consistent with the allergic hypothesis. Let us contrast this with protein-shock therapy. A fairly severe systemic shock usually does the patient no ultimate harm, the reason being that he is not allergic to the foreign protein used. For a short period the clinical condition may be improved, then a relapse occurs and the treatment has to be repeated indefinitely: in the few cases where shock treatment can be held to be successful the result is obtained after the first injection. Before leaving the matter it is as well to state that another question—non-specific desensitization—has for a number of reasons no relation to protein-shock therapy. The nature of the general and prodromal signs and symptoms of arthritis deformans is of the highest significance. Tachycardia, irregular pulse,

localized sweating, adenitis, swelling and pain around joints, muscular tremors, leucopenia with a relative lymphocytosis, increased sedimentation rate of the blood, and asthenia, are all present, and all of them are to be found in the usual type of human anaphylaxis—serum sickness. The phenomena of anaphylaxis vary according to the species of animal; but in any given species the signs and symptoms are the same, regardless of the nature of the sensitizing agent in operation. If the description of the general and prodromal features of arthritis deformans, as given by the Arthritis Committee and by various standard textbooks, be compared with the description of serum sickness by Kolmer (1923), Muir and Ritchie (1919), Zinsser (1922), and others, it will be found that the two are exactly interchangeable.

SUGGESTED EXPLANATION OF RHEUMATISM

Anaphylaxis is probably the most confusing branch of immunology, and it is necessary for the student to attune his mind to the anaphylactic concept. A suppositious example will illustrate the point. Intolerance to a drug means only that the individual develops the distinctive toxic picture with an unusually small dose, and the syndrome has nothing in common with drug allergy. The allergic syndrome of digitalis is high fever, adenitis, sweating, and swelling and pain in several joints. Bacterial anaphylaxis is considered by Amoss and Bliss (1927) to be an initial stage of general immunity, and Derrick and Swift (1927) concluded that it is an early stage of resistance in a localized focus, whilst general immunity is the response of tissues over a wide area to a reasonably maximum dose of antigen. Similarly, Bessau and Detering (1928) hold that specific cellular allergy is the primary reaction in immunity, circulating antibodies being a later effect. Nordman (1931) points out that the Arthus phenomenon offers an explanation of the endocardial lesions in acute rheumatism. Arthus (1903) found that repeated injections of sensitizing into an anaphylactic animal gives rise to increasingly severe local reactions, which may pass on to necrosis; so that any original damage done by streptococci or their toxins during the early stage of infection may leave the damaged area open to attack by the circulating sensitizing agent. The explanation implies, *a priori*, an original selective action by the organism: such is known to occur in man, because, during recovery from proved streptococcal septicaemia, a pyogenic infection of one or more joints is not uncommon. The observation of Arthus may have some relation to that of Auer (1930), who found that injury to the skin of a sensitized animal when antigen was in the circulation may produce a local allergic reaction due to the actual excretion of sensitizing into the injured area. It could be inferred from this that once a joint is damaged a more or less continuous irritation is set up by the antigen in the blood, and a vicious circle is started which can be broken only by the removal or neutralization of the circulating antigen.

Since the anaphylactic syndrome is independent of the nature of the sensitizing agent, it follows that there is nothing to prevent any organism causing the disease provided it is capable of producing allergy in man, and this may explain why cases are reported from time to time as being due to some bacterium not usually associated with the disease. A possibility that will not lessen the complexity of the whole question is that "rheumatism may conceivably be produced by the combined action of a selective toxin and a distinct sensitizing agent. They may be derived from the same organism, or two species may be in action. The hypothesis is not very far-fetched because clinical anaphylaxis is almost invariably revealed during treatment of a bacterial disease by means of horse serum containing the appropriate antitoxin. A profound alteration in an animal's metabolism may induce some variation

in the anaphylactic syndrome peculiar to the species. Fleisher and Wilhelmj (1927) studied anaphylaxis in thyroidectomized guinea-pigs, and found that, although the operation did not influence the ease of production of shock in this animal, the syndrome was modified. In man, chronic villous arthritis is the only form of rheumatism in which thyroid deficiency is clearly suggested, and in which administration of thyroid recognizably benefits most cases. The clinical variation of this disease from the general type may constitute the parallel change.

The liability to allergy in general is a weakness of the host, inherited or acquired. That the actual allergic state to some particular substance is itself truly transmitted is very doubtful, since allergy in young infants has never been shown to have been transmitted by the father. Transmission through the mother has been recorded frequently, but this is probably due to passage of sensitogens through the placenta. Ratner, Jackson, and Gruehl (1927) find that antitoxins, precipitins, and sensitogens can permeate the human placenta, and believe it to be due to the fact that the layer separating the two blood streams is only one cell thick. A hereditary liability to anaphylaxis has been found in animals, and the adduced facts may explain why rheumatism is frequently a familial disease, and may also constitute an answer to the triumphant query as to why, if pyorrhoëa is a cause of rheumatism, every sufferer from the former disease does not also exhibit evidence of the latter.

TREATMENT BY DESENSITIZATION

There are two methods of desensitization. Non-specific desensitization has been induced by a number of substances, and a list of them is chiefly remarkable for the dissimilarity of its constituent members. They range from sodium chloride to proteins, and it is certain that if each of them in turn was tried upon a sufficient number of rheumatic cases a brilliant result would be effected by each—once. In animals they are neither reliable nor permanently successful: Isaacs (1928) finds that non-specific desensitization is successful in about 50 per cent. of guinea-pigs, and that the result disappears in about twenty-four hours. Specific desensitization is the alternative and rational method. It consists in treating the animal with the sensitizing agent that caused the condition. In the case of rheumatism that substance is the bacterial antigen in its crude form, or some modification of it that will stimulate the supply of specific antibodies. The inevitable inference from this is that some type of bacterial antigen is the cardinal line of treatment, and that all the drugs employed are but adjuncts to it. A point as to the selection of an immunizing antigen arises here. Toxoid, whilst free from toxicity, is known to be a good immunizing agent, and at first sight it might be preferred to toxin, assuming that the latter was the operating sensitizing agent; but if the precipitate theory of the mechanism of shock be accepted—and much modern work suggests that it is true—then there is no reason why shock should not be produced by either substance indifferently. The antibody is already present, and one introduces an antigen which can combine with it. Common toxicity may not enter into the question.

USE OF SHOCK-DEPRESSANT DRUGS

A certain number of drugs have long been known as depressants of anaphylactic shock—that is, they can mask the severity of any particular shock and may even abort it. None, however, have any influence upon the anaphylactic state itself. The animal is just as sensitive as before. Among these drugs are salicylates, aspirin, salol, antipyrine, some narcotics and anaesthetics, calcium, magnesium, bromides, iodides, and some resins. The salicylates in acute rheumatism illustrate the limitations of shock depressants. They lower temperature and make

the patient more comfortable, but they have no influence upon the incidence of subsequent endocarditis, a result which agrees with their role in anaphylaxis. The action of salicylates in experimental streptococcal arthritis in rabbits was studied by Davis (1915), who found that they had no effect in preventing endocarditis or the localization of organisms in the joints. Moreover, they did not affect the course of the infection once it was established. His results were confirmed by Fantus, Simmonds, and Moore (1917), and substantially so again by Swift and Boots (1923). Salol has a reputation as an intestinal antiseptic in allergic diseases of the skin, and has been used in rheumatism. Yet it can be shown that its bactericidal power in the intestine is negligible. Viewed as a shock depressant its occasional successes are understandable. (It is of interest to note that in serum sickness Kolmer recommends aspirin for the muscular and neuritic pains, and sodium salicylate with bicarbonate when the joints are involved.) In lowering temperature and abolishing joint pain and swelling, atropine hypodermically is more efficient than salicylates and is equally useless for true curative purposes.

Magnesium is one of the commonest constituents of spa waters, and it is a depressant of unstripped muscle, the reaction of which is one of the basic anaphylactic phenomena in all animals. But it is possible that its utility as a remedy does not end there. In man fatal cases of anaphylaxis permitting post-mortem examination are rare, but Dean (1922) found that the liver cells were much injured, and was able to confirm Weil's view that dilatation of the hepatic capillaries is an important factor in human shock. Parallel to that is the finding of Mendenhall, McClure, and Cate (1926) that magnesium sulphate in small doses is a true cholagogue, and it is therefore not unreasonable to suppose that the daily action of small doses may assist the liver in its resistance to anaphylactic irritation. The intake of great quantities of water, with some small proportion of dissolved salts, may also be advantageous, since Raulston (1927) has shown that during shock anaphylactic rabbits mobilize water and electrolytes from the tissues. It is believed that many of the simpler sensitizing agents, such as iodine, owe their effects to combining with a protein of the host, and in so doing altering it sufficiently to cause it to act as a foreign protein: this is supposed to be particularly true of iodine. Klopstock and Selter (1927) used diazotized atoxyl with serum, and considered that the mixture reacted with natural proteins to give a denatured protein changed enough to act as a foreign protein. (The activating agent of a shock can be very simple. Thus Smetana (1927) sensitized animals to haematoporphyrin and shocked them by exposure to sunlight.)

The bearing of the foregoing observation upon rheumatism is on the question of desensitization. It has been found by many workers that if a substance capable of sensitization be administered to an animal, anaphylactic to another sensitizing agent, a few hours before a shock dose of the animal's sensitizing agent is given, then the shock is frequently averted. This action may explain the beneficial effects of iodine in arthritis deformans, the action being one of non-specific temporary desensitization. However one chooses to regard the action of iodine, it is a fact that its beneficial effects are chiefly seen in the chronic infective diseases which are considered to have an allergic factor in their pathogenesis—namely, syphilis, yaws, tuberculosis, and disease due to the higher vegetable parasites.

CONCLUSION

The parallelism that exists between the syndromes of the two diseases—anaphylaxis and rheumatism—and between the drugs used in their treatment are, when itemized, far too numerous to be dismissed as a series of co-

incidences. There being no other theory that will account for all the phenomena of rheumatism and its treatment, I submit that the anaphylactic explanation must be accepted as the only alternative to a position that is no more than a contradictory muddle of mysteries.

A dictum of Kolmer is a fitting conclusion: "Under proper conditions it is reasonable to suppose that anaphylactic shock or shocks may occur during the course of a given disease, and that the effects of these may contribute to the lesions and symptomatology in no small degree."

THROMBOSIS, EMBOLISM, AND THEIR TREATMENT

BY

GEORGE BANKOFF, M.D., M.S.

HONORARY SURGEON, ST. JOSEPH'S HOSPITAL, MANCHESTER

With the recent progress of surgery, especially in major operations, there has been an increase of thrombosis and embolism, constituting an ever-present threat to the success of such operations. With this fact in mind I conducted experiments directed towards an inquiry into the cause of these pathological conditions. The results have been published by the *Klinische Wochenschrift*, 1932, ii, 502. On account of the interest taken in this work I will set forth the method of treatment which I have found very successful in the practical application of the principles established therein.

THEORIES OF CAUSATION

Before entering into details of the treatment we must discuss briefly what is the origin of thrombosis, so that it may be determined in which patients the disease is likely to occur. On this point scientific opinion is divided into two main groups—one believing it to be due to bacterial infection, and the other to a special constitutional predisposition. The first group—the supporters of bacterial infection—have reported cases of thrombosis and embolism in which they have tried to prove conclusively that certain infectious diseases are the cause of the

thrombosis. In the majority of cases the cause of infection was attributed to such non-virulent bacteria as the organisms found in influenza, bronchitis, etc., and in cases in which it was impossible to demonstrate any definite organism it was explained that the disease was due to some unknown ultra-filterable virus. The principal advocates of the germ theory—Franke, Kuskow, Kinzel, and Pathy—while subscribing to it in a general way, differ slightly in their conclusions. Either they believe thrombosis to be a direct result of bacterial action or they think that the virus or its toxin affects the individual, producing irregularity in the blood circulation, hypotonia, and damage to the blood vessels, thus giving rise to thrombosis.

The second group deny that infection has any connexion with thrombosis. The supporters of this theory—Payr, Morawitz, and especially Rehm, who is its founder—believe that all patients affected by thrombosis belong constitutionally to one type. They call this condition thrombopathy, and emphasize that in all such cases the patients are found to have a special construction of the sympathetic nerve system. Some members of this group qualify their opinion by stating that thrombosis may be due, not necessarily to a permanent, but to a temporary, difference in this system. Others—Koenig, for instance—in cases in which no cause can be found for thrombosis, nevertheless deny it to be the result of an infection. It is not my intention to criticize this theory at length, but I believe from the experiments I have made that it is absolutely wrong to state that there is a special idiosyncrasy which gives rise to thrombosis, because, if this were admitted, it would be impossible to explain why a patient, operated on two or more times, on one occasion suffers from thrombosis and on another does not, and why the conditions for thrombosis are not present at each operation. If we admit that temporary damage to an organ can bring about thrombosis, why must we exclude damage from a germ? To explain further: if damage to the intima of the blood vessels can produce thrombosis, that damage may arise from bacterial action. It cannot therefore be denied that infection may be a direct cause of thrombosis. On the other hand, one cannot agree with the supporters of the germ theory who believe that thrombosis is due only to infection. There are many cases in which it is absolutely impossible to find any organism, and in which, on the contrary, it is easy to find some special organic construction. The presence of a non-visible germ in these cases is not an acceptable theory.

METHOD OF DETECTING LIABILITY TO THROMBOSIS

I now wish to emphasize my opinion that thrombosis can never be regarded as due to only one class of causes: it is a pathological state which can arise from different causes at any time the equilibrium of the patient is destroyed. (It is irrelevant to discuss here the aetiology of this destruction of the equilibrium.) I do not believe that all patients are liable to thrombosis. In order to be affected by this condition it is not enough to have present the causes for producing it. I divide patients into two groups. In the first and, fortunately, the largest are the patients who can never suffer from thrombosis, even if the organs are damaged. In the second group there will always be a risk without any external influences. In making my experiments my intention was to find a means of detecting which patients can be affected by thrombosis and which can not. I began to search for some agent which would produce definite symptoms enabling me to divide the patients into two groups: those predisposed to thrombosis, and those whom I believed to be immune to it. After long and involved experiments it was possible to demonstrate that by the hypodermic injection of thyroxine the reaction of each group was different.

The method I have adopted is as follows. Two days before the operation all patients are injected with 1 c.cm. of thyroxine. After three hours the temperature, pulse, and blood are examined. In the first group, which may be termed "thyroxine-sensitive," as a result of the injection, the pulse quickens and the temperature rises slightly; difference in the blood composition is noticeable by the variation of the quantity of the blood corpuscles—the number of the red corpuscles increases slightly, whilst the number of blood platelets decreases. After two or three injections of thyroxine these become two or three times more abnormal, and the time necessary for blood coagulation is longer. On a patient in this thyroxine-sensitive group any external influence, especially the operation itself, will produce the effects mentioned above, and for this reason I do not believe they can be affected by thrombosis. In patients in the second group, termed "thyroxine-resistant," as a result of the same injection it is impossible to detect any change in temperature, pulse, or blood composition. A slight variation in blood corpuscles is sometimes noticeable, but is of no importance. To these patients every operation will bring the danger of thrombosis.

The scientific explanation of the reaction to thyroxine is explained in different ways. Freund and Boshamer believe that the thyroxine acts on the vegetative nervous system, and at the same time directly affects the cardiovascular system, producing the clinical symptoms in the patient. In the thyroxine-resistant group of patients the effects of the injection are almost unnoticeable, because the systems mentioned above show very little reaction. In this group of patients the parasympathetic nerve system predominates, thus facilitating the formation of thrombosis. During the last three years I have experimented with more than two thousand patients admitted for operation. In every case thyroxine was administered and the patient afterwards examined. In this way patients were divided into two classes: thyroxine-sensitive and thyroxine-resistant.

PREVENTIVE TREATMENT

After the thyroxine effect had been discovered it was necessary to find some treatment to prevent thrombosis. During this experimental period all cases in which thrombosis occurred were examined and were found, without exception, to belong to the thyroxine-resistant group. This tended to confirm my conclusion that only patients of this group were liable to thrombosis. The treatment that was found to be successful consisted in the administration, hypodermically, of a combination of atropine and ephetonin in the proportion of 1/100 grain atropine to 1/4 grain ephetonin. Not less than three injections in all were given every other day, beginning from the fifth day after the operation. I am able to state that not one patient treated in his way suffered from thrombosis or embolism.

The scientific explanation of the influence of atropine and ephetonin is as follows. With the first injection a variation in the blood composition is noticeable. Six hours after the injection the number of blood platelets is less than 100,000 per c. mm., and the number of red cells is slightly increased. The decrease of blood platelets occurs after every injection until the third, when the same level is maintained. The time necessary for coagulation of blood is two or three times longer than usual. This is shown more clearly in the diagrams.

In small hospitals where there is no laboratory equipment and it is thus impossible to divide the patients into thyroxine-sensitive and thyroxine-resistant, I believe it is advisable to treat all patients as belonging to the latter division. The injection of atropine and ephetonin can never be harmful to the patient, and is even useful for

the prevention of post-anaesthetic lung trouble. In this way mistakes will be avoided and deaths from thrombosis will be reduced to the minimum.

CHART 1.—Thyroxine-sensitive patients.

CHART 2.—Result of ephetonin-atropine treatment of "thyroxine-resistant patient."

SUMMARY

The origin of thrombosis is not confined to one group of conditions. It is rather a special pathological state due to external influences such as constitutional predisposition, bacterial infection, or toxæmia. Not all patients are affected by the thrombosis, but by the use of thyroxine it is possible to divide them into two groups: those immune from, and those predisposed to, thrombosis. The symptoms which demonstrate the difference between the two groups are the pulse, temperature, and variations and change in the blood composition. The treatment is the hypodermic administration on alternate days, beginning on the fifth day, of a combination of ephetonin and atropine.

TORSION OF THE NORMAL FALLOPIAN TUBE

BY

ALISTAIR McEACHERN, M.B., B.S., F.R.C.S.Ed.
RESIDENT MEDICAL OFFICER, KING GEORGE HOSPITAL, HILFORD

Torsion of abnormal uterine appendages is not an uncommon condition, but torsion of normal appendages is much less frequently encountered. Torsion may involve either the normal tube or the normal ovary, or both; but this brief review is confined to tubal torsion, of which the following is an example.

A girl, aged 14, was admitted to King George Hospital on April 5th, 1931, under the care of Mr. Harold Dodd. Pain in the right lower quadrant had begun four days previously. After twenty-four hours it had become central, and vomiting occurred. The pain persisted and remained central. The bowels had acted on the day of admission, and there were no urinary symptoms. The first menstrual period had begun on January 1st, 1931, and had lasted seven days; the second, on February 4th, lasted four days; and the third, on March 8th, lasted four days. (The fourth began on April 6th, twenty-four hours after the operation, and lasted two days.) Since the age of 2 she had suffered from attacks

of pain in the right iliac fossa, associated with headache. These attacks lasted three to four days, beginning and ending suddenly, and were usually associated with vomiting. Up to the age of 7 they occurred every one to two months, but subsequently they had become much less frequent.

On admission her temperature was 98.8° F. and her pulse 86. There was well-marked tenderness and rigidity in the right lower quadrant. Nothing abnormal was noted on rectal examination, and the urine was normal. A diagnosis of acute appendicitis was made, and the abdomen was opened by a gridiron incision. The appendix appeared to be mildly inflamed, and was removed. A mass was then detected in the right side of the pelvis, necessitating exposure through a right paramedian incision. This proved to be the right Fallopian tube, which had undergone two complete turns in an anti-clockwise direction (see Fig.) It was dark red and

Acute torsion of the right Fallopian tube.

much enlarged, due to swelling of its walls and haemorrhagic effusion into the wall and lumen. The mass was 5 cm. long and 3 cm. in diameter. It was removed, and the wounds were closed in layers. Recovery was uneventful, and the patient was discharged from hospital on the fourteenth day. The specimen was submitted for examination to Dr. Arthur Davies, who reported that there was no evidence of pregnancy, and that the haemorrhagic effusion was the result of torsion. In the two years which have elapsed since the operation there have been two attacks of pain somewhat similar to those which occurred in childhood.

In my opinion the interesting features of this case are:

1. The history of recurrent attacks of pain. This has been a feature of some of the recorded cases, but in this instance it seems probable that the repeated attacks were due to some other cause.
2. The definite relation to the pre-menstrual period.
3. The anti-clockwise direction of the twist, which is the reverse of that which is said to be usual on the right side. Kustner's law (quoted by Downer and Brines¹) says that, in torsion of uterine adnexae, twisting on the right side is clockwise and on the left side anti-clockwise.

The factors concerned in torsion of the Fallopian tube have been discussed from time to time in the gynaecological literature of the last twenty years, and a number of theories have been advanced to explain why a normal tube should suddenly undergo axial rotation to a pathological extent. It has been suggested that the tube is only apparently normal, and that it has been the seat of a mild inflammatory process, possibly associated with a slight hydrosalpinx. It is postulated that this may have resulted from vulvovaginitis in childhood, or that it may have occurred as a complication of one of the exanthemata.^{2,3} To reduce to a minimum the possibility of a low-grade infection of Neisserian or puerperal origin, this review is confined to torsion of the Fallopian tube in virgins. It would appear that in the recorded cases no very definite evidence of antecedent disease has been

found, and in the present case there were no adhesions and no suggestion of hydrosalpinx. I think, therefore, that it is probable that a tube indistinguishable from the normal can undergo torsion. Unusual mobility of a tube due to unusual length of the tube itself, the fimbria, or the mesosalpinx would predispose to unnatural twists; but in addition to a predisposing anatomical condition some further factor would be necessary to precipitate acute torsion.

Association in some way or another with menstruation occurs so frequently in the recorded cases that it would appear to have some aetiological relation. In this connexion two aspects of the menstrual function are of particular interest: first, it is conceivable that the passive congestion at this time may be one of the factors concerned; and secondly, it has been observed that during menstruation the tube occasionally contains menstrual blood. That this does sometimes happen has been established by Sampson,⁴ Bailey,⁵ and others; and it is generally believed that it is the result of regurgitation from the cavity of the uterus. Another view is that it arises by a process of tubal menstruation,⁶ but although this would appear to be embryologically possible it has never been proved to take place. The presence of blood in the tube may be concerned in the origin of torsion in one of two ways: it may be responsible for, or associated with, the initiation of abnormal contractions of the tube, or the simple factor of weight may be of importance. It is interesting that at least ten of the cases referred to have occurred after puberty, whereas torsion of the ovary or ovary plus tube before puberty is by no means unknown.

Another aetiological factor which has been commented upon is that of strain or sudden movement, but this does not appear to occur so frequently as association with menstruation. The most reasonable explanation of the way in which strain might be concerned in the origin of torsion is that contained in the haemodynamic theory of Payr, which is quoted by Gabe⁷ and Thorek.⁷ Payr showed, by injecting the vessels in the pedicle of the spleen, that torsion was imparted as a result of the spiral course of the vessels. It is conceivable that a sudden rise of pressure in tortuously disposed vessels may be a factor in torsion of the Fallopian tube, even though the anatomical arrangements are different from those obtaining in the pedicle of the spleen.

It would appear from these considerations that the important factors in the aetiology of torsion of the normal tube are anatomical predisposition, association with menstruation, and strain or sudden movement.

In the literature at my disposal I have found records of nine cases of torsion of the Fallopian tube in virgins. (1) Stark,⁸ 1911. Aged 46. Three previous attacks. Dermoid right broad ligament. Torsion left tube. (2) Davies,⁹ 1925. Aged 19. Clockwise torsion right tube. Long mesosalpinx. Association with menstruation. (3) Rogers,¹⁰ 1925. Aged 16. Torsion right tube, also left to less extent. Menstruating. (4) Darnier,¹¹ 1926. Aged 13. Clockwise torsion right tube. Menstrual period began five days after operation. Onset of pain followed a kick. (5) Jefferson,¹² 1926. Aged 32. Clockwise torsion right tube. Long mesosalpinx. Menstruated two days after operation. (6) Gillies,¹³ 1926. Aged 23. Torsion left tube. Last period two weeks previously. (7) Corlette,¹⁴ 1927. Aged 20. Clockwise twist of left tube occurring while confined to bed following fracture of tibia. Tube enormously distended. (8) Koster,¹⁵ 1929. Aged 16. Torsion of right tube. Menstruating. (9) Michon,¹⁶ 1930. Aged 26. Torsion of left tube. Koster¹⁵ gives references to five further cases reported by Auvray, Schweitzer, Hausen, Heil, and Gabe.

SUMMARY

1. A case of torsion of a normal Fallopian tube in a virgin is reported.

2. Nine other cases have been found in the literature, in addition to five quoted by Koster.

3. The aetiology in general is discussed, the salient points being preternatural mobility, association with menstruation, and strain or sudden movement.

My thanks are due to Mr. Harold Dodd for permission to publish this case.

Memoranda

MEDICAL, SURGICAL, OBSTETRICAL.

COMPLICATIONS FOLLOWING ANAESTHESIA WITH SODIUM EVIPAN

The case to be described is the only one in a series of 150 in which complications have followed the use of sodium evipan. It is of interest by reason of (1) the long latent period before the onset of symptoms, and (2) the toxic manifestations not being those commonly associated with poisoning by drugs of the barbituric group.

The patient, a man aged 23, was admitted to the hospital for the excision of a sebaceous cyst from the scrotum. There was some ptosis of the right eyelid, which had been present since birth, and atrophy of the right testicle, presumably due to mumps; otherwise he was apparently healthy and normal. Following my (E. L.) usual practice no preliminary medication was employed, anaesthesia being induced with evipan 10 c.cm. and supplemented with gas-oxygen anaesthesia. The cyst was removed, the course of the operation being uneventful. When the patient returned to consciousness about half an hour after the operation he was very restless; he was restrained, and there is no evidence that he injured himself in any way during that period. Eight hours later he was still restless, and was suffering some discomfort; 1/4 grain of morphine was injected and sleep ensued.

The following morning the patient appeared well, but complained of some headache; he was able to read, and took his food well. This persisted throughout that day, the following day, and until 9.30 on the evening of the third day, when he complained of sudden severe frontal headache, giddiness, spots before the eyes, and photophobia. The pulse rate dropped to 40; the temperature and respirations remained normal. He was seen by a colleague, who prescribed 1/50 grain of atropine and 10 minims of adrenaline. The pulse rate rose to 50, and the patient slept. On the morning of the fourth day he was somewhat drowsy, and lay back with neck and legs flexed. The temperature and rate of respiration were normal; the pulse rate was 36. The heart showed no signs of organic disease, and the blood pressure was 135/80. The pupils reacted to light and accommodation, but there was lateral nystagmus to the left. There was no evidence of paresis or anaesthesia in any part of the body. All tendon jerks were exaggerated, and the plantar response was flexor on both sides. The abdominal reflexes were brisk, and dermatographia was marked. Kernig's sign was negative, and the disks appeared normal. There were no sensory changes. The liver was not enlarged, and there was no jaundice. The urine contained no albumin, blood, sugar, or acetone bodies. Lumbar puncture was performed, and a clear fluid under slightly increased pressure was obtained. The manometer reading was 170 mm., 25 c.cm. of fluid being withdrawn. This fluid on examination revealed no excess of cells, no organisms, and

normal content of sugar, albumin, globulin, and chlorides. An electrocardiogram showed no abnormality. The nystagmus disappeared after the lumbar puncture.

On the fifth day the patient was still drowsy, and complained of occipital headache. The blood pressure was 140/85, and the pulse rate varied during the day between 40 and 50. Towards the end of the day the nystagmus reappeared, and the patient vomited twice. On the sixth day the patient's condition remained the same. The vomiting had become persistent, and he was unable to retain any food. Hypertonic glucose was given intravenously, and later in the day the blood pressure was found to have fallen to 120/70. The injection of hypertonic glucose was repeated on the seventh day, the vomiting ceased, and the headache became less severe. Eight days after the operation the pulse rate rose to 60, and the blood pressure fell still further to 115/60. There was no vomiting or headache, and the nystagmus had disappeared; the tendon reflexes remained brisk. From that day onwards the patient made an uninterrupted recovery, and was discharged on the sixteenth day after the operation. His pulse rate remained low, between 50 and 60, until two days before his discharge.

An x-ray examination of his skull showed no evidence of any abnormality or injury. The Wassermann reaction of his cerebro-spinal fluid was negative. It is difficult to assign a head injury as the cause of the symptoms; in these circumstances they can only be attributed to the sodium evipan.

We wish to thank Mr. Fedde Fedden, senior surgeon, St. George's Hospital, and Dr. Anthony Feiling, physician, St. George's Hospital, for their advice and help in the treatment of this case, and for their permission to publish these notes.

House-Surgeon, St. George's Hospital.

FRACTURE OF FEMUR IN A WOMAN OF 80

This case seems to warrant recording because of the age of the patient at the time of the accident, and the satisfactory anatomical and functional state that has resulted after treatment.

In July, 1931, the patient, a woman of 80, fell heavily on a hard floor, and when I saw her, within two hours of the accident, it was obvious that there was a fracture of the right femur in the neighbourhood of the neck. She was moved carefully to bed in an adjoining room. An x-ray photograph was taken in her own bed the following morning by means of a Philips portable x-ray apparatus, and a paratrochanteric fracture of the right femur was demonstrated. A Thomas splint was applied to give temporary extension during transit, and the patient was removed with extreme care to the Butterfield Cottage Hospital, Bourne. On the following day a general anaesthetic was given, and the limb was fully abducted, extended—that is, protracted, while the foot was internally rotated—and a plaster-of-Paris spica applied. After four days had elapsed and on each day during her stay in hospital she was lifted from bed and placed in as upright a position as possible on a reclining chair. She was sent home ten days after admission to hospital.

After three weeks from the time of the accident the ankle was liberated and movements encouraged, and after a further three weeks the knee was liberated and again movements instituted. Three months from the date of the accident the patient was allowed to bear weight on the affected limb, and to walk as best she could, wearing the plaster case. In the week before Christmas the plaster cast was entirely removed, this being five months from the time of fracture. She was then able to move about almost unaided. There is now no disability, and the patient speaks of the right leg as being her "best leg."

It seems to me that several factors contributed towards the successful result: first, knowledge of the exact lesion, from the x-ray photograph taken in the patient's own bed without disturbance before removing her to hospital;

secondly, making the period of recumbency as short as possible, which was done because of the patient's age and consequent liability to pulmonary complications; and thirdly, the early weight-bearing, which would appear to have justified the risk taken in allowing it.

It seems hardly necessary to mention that the treatment outlined above is in no way suggested as suitable for any sort of routine treatment.

Bourne, Lincs. W. B. R. MONTEITH, F.R.C.S.Ed.

TREATMENT OF AN UNCOMMON OBSTETRIC DIFFICULTY

This case may be of interest on account of the treatment of an uncommon obstetric difficulty.

A primipara, aged 24, was admitted to the Sussex Maternity and Women's Hospital, Brighton, at midnight on September 21st, in the second stage of labour, with the presenting part wedged in the pelvis. The provisional diagnosis was "impacted breech." She had been in labour for forty-eight hours. On examination under anaesthesia it was found that the presenting part was a well-moulded "brow," with its sagittal plane in the maternal coronal plane and the occiput to the right. It was disengaged from the brim and the head flexed bimanually until the occiput presented. As there was a strong tendency to revert to the brow presentation Willett's forceps were applied to the scalp over the occiput, giving it slight anterior bias. A weight of 1 lb. was attached to the handles, and the head was left to remould in its new attitude. After three and a half hours the head had descended again. The patient was re-anaesthetized, Willett's forceps removed, and the head delivered with obstetric forceps as a right occipito-anterior.

The infant weighed 6 lb. 12 oz., and breathed normally. Red marks and the spike holes could be seen where the scalp had been nipped. This area was covered with elastoplast, which was left to come off, the scalp having then healed. The puerperium was uneventful.

I wish to thank Dr. Cairn for permission to publish the case, and for his very kind constructive criticism of this account.

Brighton.

L.R.C.P.

THE FORMATION OF GALL-STONES

In an article published in the *British Medical Journal* of May 20th, 1933, Mr. D. H. Patey asked for information which would help him to decide the minimum time required for gall-stones to form in the gall-bladder. The following case is instructive, as it shows that well-defined cholesterol stones can certainly develop in twelve months, and probably in three months.

Mrs. R., aged 38, was admitted into the Ninian Hospital on March 6th, 1929, complaining of flatulence and pain in the epigastrium and right iliac region. There was no history of biliary colic or jaundice. Examination showed slight tenderness in the areas complained of. On March 7th, 1929, I opened the abdomen by a right paramedian incision and removed a fibrosed appendix and also two gall-stones, 1 1/2 in. in diameter, from the gall-bladder. There were no other gall-stones present. The gall-bladder was closed by two rows of catgut sutures, and the abdomen closed without drainage. She was discharged on March 27th, 1929. Within three months of leaving hospital the patient commenced having typical attacks of biliary colic. These got worse, and on March 4th, 1930, she was admitted into the Royal Infirmary. Renal calculi were excluded by x rays. On March 6th, 1930, I reopened the abdomen and removed the gall-bladder. It contained over a dozen cholesterol stones 1/8 to 1/4 in. in diameter. Convalescence was uneventful, and she left hospital on March 28th, 1930.

D. J. HARRIES, M.D., D.Sc.,

Surgeon, Cardiff Royal Infirmary.

British Medical Association

CLINICAL AND SCIENTIFIC PROCEEDINGS

NYASALAND BRANCH AVITAMINOSIS A

At the annual meeting of the Nyasaland Branch for 1933 Dr. S. B. SINGH read a paper on avitaminosis A, with special reference to the facilities for investigating the problems in this connexion in the Tropics. Dr. Singh said that the vitamin concerned in the particular function of keeping the epithelial membranes which lined the various passages of the body intact and resistant to infections was vitamin A, one of the fat-soluble group, and related to D. Its precursor, carotene, was present in plants, the amount being regulated by the solar rays, and so being subject to seasonal variations, which were in their turn responsible in some measure for the seasonal oscillation of infectious diseases. In the body this vitamin was stored in the liver, and to a lesser extent in the kidneys, but, unlike vitamin D, could not be manufactured in the body by the agency of sun rays, and so required to be renewed daily. It was thermostable and, with a minimal protection from air, milk did not lose its vitamin A content to any appreciable extent on boiling, although oxidation destroyed it even at low temperatures. Irradiation with certain wave-lengths could synthesize it from its precursors; other wave-lengths would destroy it. Too prolonged irradiation of foodstuffs enriched them as regards vitamin D, but made fats go rancid, and simultaneously lowered their vitamin A content.

After referring to the experimental work which had revealed the importance of this food factor, Dr. Singh dealt in detail with the effects of avitaminosis A in man. The resulting clinical picture, he said, was very puzzling, owing to the simultaneous occurrence of other grave nutritional deficiencies. Lack of the vitamin in the maternal milk retarded growth in the infant. The earliest signs of avitaminosis A, which appeared in the conjunctival epithelium, had been inadequately appreciated, owing to the fact that high degrees of this deficiency were rare in Western countries, where the staple diet contained much bread-and-butter. In India the basis of the diet was dal and bhat, or roti, and the dull, lustreless, muddy eyes of ill-fed children were strikingly obvious in village schools. The exposed part of the bulbar conjunctiva, as the result of keratinization, became thick, fatty-looking, and of a dirty yellow colour, wrinkling into coarser folds when the eyeballs moved laterally. A thin, translucent band of stratified squamous epithelium, seldom broader than 1 mm., encroached upon the upper part of the cornea from the limbus. In more advanced cases the lower edge of this band was often fringed with a number of pin-point pits, representing minute areas of superficial ulceration. The keratinization might later affect the conjunctiva of the fornices and lids, the lower being first affected. If the dietary deficiency continued, there was an attempt by the conjunctival cells to develop pigment in their basal layers—a reaction which aimed at protecting the weakened retina from light. At such a stage the normal function of the retina was almost always lost, and the patient complained of night-blindness; all these signs and symptoms cleared up in a few months with better feeding. A similar but deeper shade of pigmentation of the eyes appeared in cases of chronic malaria, and was due to the deposit of melanin. Examination with the loop showed that the melanin was distributed in a short, curved streak or coarse spots, while the pigmentation of avitaminosis A was lighter, and was uniformly distributed in the deeper cells of the more exposed parts of the conjunctiva. The fatty appearance was caused by the keratinization and desquamation of the surface cells. On the other hand, pterygium was discernible by the fine blood vessels running through it. Pinguecula, again, affected the elderly, and was usually more marked on the nasal side. The translucent band on the cornea might be confused with the pannus of trachoma, a disease which affected the well nourished as

well as the underfed. Pannus, also, had streaks of blood vessels running through it. With continued lack of vitamin A the eye changes progressed, and ultimately reached the well-known stages of xerophthalmia and keratomalacia.

The epithelium of the respiratory system lost its integrity and vitality in hypervitaminosis A, with the consequent appearance of catarrhal conditions, sinusitis, adenoids, discharging ears, and bronchitis. The degeneration of the ciliated epithelium brought the lungs within easy reach of pathogenic organisms, and pleuritis and pneumonia followed. *Pyorrhoea alveolaris* was also induced to a considerable extent by lack of vitamin A. In advanced cases the salivary and other glands showed ducts choked by the shed keratinized debris, and atrophied subsequently. The mouth became dry, and aphonia followed. With involvement of the glands of the digestive tract gastro-enteritis and colitis ensued. In the urinary system keratinization provided a nucleus for calculus formation. This was furthered by the deposit of calcium phosphate, caused by self-induced hypervitaminosis D in an attempt to cure the general ill-health by ultra-violet irradiation and the administration of this vitamin. The genito-urinary tract invariably became inflamed in such circumstances. Demyelination of the peripheral nerves explained many of the nervous disorders which were so frequently encountered in cases of avitaminosis A. The irritability of the nerves was further accentuated by the associated hypovitaminosis D disturbing the calcium and phosphorus metabolism. Under such conditions the nervous system was easily overpowered by the low-grade toxins produced within the body or introduced into it. The convulsive ergotism in rye-eating communities, and lathyrism in the lathyrus-pea-eating tribes of India, occurred in times of famine and drought, when there was scarcity of dairy products and vegetables, and consequent avitaminosis A. Such degenerative conditions of the spinal cord were also met with in Addison's disease, beri-beri, pellagra, epilepsy, and the cachexia of cancer, and it was quite possible that a lack of vitamin A might play some part in these diseases. The administration of liver, which was rich in this vitamin, caused great improvement in the cord in pernicious anaemia. The improvement in cases of general paralysis treated by malaria therapy was probably traceable to the release of large amounts of vitamin A latent in the liver. These and other possibilities deserved closer attention and more intense investigation. There could be no doubt that vitamin A had pronounced antibacterial properties; deficiency of it induced cellular deterioration and an upset of the normal activities of the reticulo-endothelial system. It did not act alone, however, in preserving the general health, for both vitamins B and D were often associated, but its study had thrown much light on many baffling borderline states of ill-health. It was usually the case that an Indian child, after weaning, was improperly fed, and it was not sufficiently widely realized that the pregnant Indian woman needed an ample supply of vitamin A for the foetus as well as for herself. During the physiological readjustments of metabolism at puberty and the menopause the reserves of vitamin A soon became exhausted and, if not replenished adequately, paved the way for infections. Intensive administration of this vitamin was of great value in many diseases and their convalescent stages. In certain disorders, such as pyrexias, obesity, acidosis, asthma, and some skin diseases, the ingestion of fat had to be limited, but this should not be allowed to lead to hypovitaminosis. In the treatment of kidney disease, for example, when diets rich in protein and poor in fluid were required, milk should be given as curd, and not be cut out of the diet. It must also be remembered, added Dr. Singh, that in certain cases of defective absorption of fat the diet might be adequate but the bile or pancreatic secretion be deficient. This occurred in obstruction of the ampulla of Vater or the duct by tumour or inflammation of the pancreas, in interference with the flow through the intestinal lymphatics: in gastro-colic fistula; in sprue; and in coeliac disease. Many artificially prepared concentrates of vitamin A were now available, and these should be used in conjunction with other vitamins, especially B, when indicated by the clinical condition.

Reviews

ABDOMINAL AND RECTAL OPERATIONS

This well-produced and superbly illustrated volume, *Operative Surgery: The Abdomen and Rectum*, by Professor MARTIN KIRSCHNER, is really the second of a series which, when complete, should cover the science and art of operative surgery in a manner never before attempted. It is well translated from the German by Dr. Ravdin, who pauses occasionally to introduce (in brackets) his own views, which do not necessarily accord with those of the distinguished author, but he naturally gets the last word.

There is nothing to criticize; we can only express amazement at the immense industry, the infinite care, and the wide knowledge which every page reveals. This is a book on the heroic scale, and is not for the beginner; but those who seek adventure on the higher slopes of surgical endeavour will find what they require here. The Kirschner thoraco-laparotomy, the excision of stoma ulcers involving the colon, and the surgical exposure of the oesophagus are examples of some of the operations described. This is the "big stuff" of surgery, but the author does not neglect the minutiae of more everyday proceedings, and there is much of value that cannot be obtained elsewhere. In what other textbook of operative surgery would one find, for instance, a consideration of the calorie value of jejunostomy feeds? Among many matters that will especially interest the practical surgeon is the stress laid upon the value of such mechanical aids to surgery as the Petz suture instrument, which is claimed to have "given gastro-intestinal surgery a new angle"; and the electro-surgical knife, which is stated to have "brought about a veritable transformation in gastro-intestinal surgery." It is interesting also to note such divergences from current British practice as the use of silk for intestinal suturing, and of silver wire for tension stitches. Intriguing, too, and strange to our eyes is the author's use of rubber condoms for the temporary closure of the bowel ends during the course of intestinal resection.

This is certainly a great book, which reflects the utmost credit on all concerned in its production. In his preface to the present volume Martin Kirschner rather pathetically states that German science and German texts are struggling for recognition in the world, but the reception this book is certain to receive from the world of surgery ought to make him a happy man.

CUTANEOUS NEOPLASMS

Largely owing to climatic reasons Australia enjoys a regrettable pre-eminence in the frequency of cutaneous neoplasms among its inhabitants. Dr. NORMAN PAUL, who is dermatologist to Sydney Hospital, has had exceptional opportunities for studying them, and has crystallized his observations in the form of a convenient little book¹ furnished with plenty of illustrations. He deals both with the various forms of malignant disease and also with the less serious but interesting growths, such as adenoma sebaceum, granuloma annulare, etc.; but the part of his book which will attract the greatest interest is that concerned with various forms of new growths associated with the strong sunlight that beats upon the Australian scene.

¹ *Operative Surgery. The Abdomen and Rectum*. By Professor Martin Kirschner. Authorized translation by I. S. Ravdin, B.S., M.D. London: J. B. Lippincott Company. 1933. (Pp. xiv + 529; 325 figures. 50s. net.)

² *Cutaneous Neoplasms*. By Norman Paul, M.B., Ch.M. London: H. K. Lewis and Co., Ltd. 1933. (Pp. xii + 154; 62 figures. 10s. 6d. net.)

The epithelial triad, as it has been called, consists of keratoses, rodent ulcer, and epithelioma, and they owe their frequency to the fierceness of the Australian sun. Up to the present time they have been observed for the most part among agriculturalists and others whose occupation necessitated long periods of exposure to the sun. In recent years, however, the popular practice of sun bathing has led to the appearance of these pathological changes in the skin among the numerous individuals addicted to this pursuit, and the author warns them seriously against the danger of the damaging effect of strong and continuous sunlight upon a skin insufficiently protected by pigment. The first sign of trouble is the condition which is termed "dermatitis solaris chronica." It is a degenerative condition of the skin characterized by irregular macules of pink or brownish pigmentation, and by keratoses, which may ultimately develop into malignant neoplasms. Fair-complexioned persons, the least protected by melanin, are the most susceptible, and Dr. Paul says that the condition is a very prevalent one in Australia.

Is there any need for the sun bathers of Great Britain to take warning? Probably not. Sunlight in this country is neither so powerful nor so consistent as that in Australia, and in all likelihood we may continue to take advantage of all we can get of it without risk of developing cutaneous cancer in our old age.

ŒUVRES DE PASTEUR

The first five volumes of the edition of the Works of Pasteur¹ which is in course of publication by Masson and Cie, under the editorship of Professor VALLERY-RADOT, have already been referred to in the *Journal* of June 29th, 1929. Volume six has now been issued, and there remains only a single volume to complete the work. This splendid edition includes not only a transcript of the formal announcement and description of Pasteur's discoveries, but also an account of the various stages which led up to the discoveries, together with the criticisms and discussions to which they were subjected at the meetings of the Académie de Médecine and the Académie des Sciences in which Pasteur himself took part. It contains, therefore, in Pasteur's own words, and with incomparable clearness, the history of every step leading to the revolution which he effected in medical and surgical thought; and it will probably also form an important source from which an insight into Pasteur's personality is to be obtained. The idea from which Pasteur started is expressed in a characteristic manuscript note of his dated 1859.

"When the struggle of life and death leaves the latter victorious the dead plant or animal undergoes fermentative changes which gradually reduce its parts to the simple combinations which enable its elements to re-enter into the unending cycle of life and death. Everything indicates that infectious diseases owe their existence to causes of a similar nature."

Pasteur had already refuted Liebig's theory of fermentation; he had shown that micro-organisms were the essential cause of the process, and foresaw the significance of that fact in its bearing on the nature of infectious disease. At the time, the theory of the spontaneity of contagious disease was, according to Professor Bouillaud, dying out in France: specificity was recognized, but the cause was attributed to miasms; microbes had been detected in a few diseases, but a causal connexion was unsuspected or denied. On the other hand, fermentation was known to be sometimes associated with micro-organisms, and in many forms the latter appeared to be absent, and when present

were regarded merely as an accidental contamination. Pasteur showed that micro-organisms, derived from the exterior, were the essential causes in both cases; the important results that immediately followed, together with the germ-theory of disease based on the discovery, form the main subject-matter of the volume now published.

The first two of the fourteen sections into which the volume is divided contain the discussions held at the Academy on putrefaction and fermentation; the following section relates to Guérin's communication on cotton-wool dressings; the fourth to the theory of germs and its application to medicine and surgery, especially in relation to puerperal sepsis, furunculosis, and osteomyelitis. The fifth section deals with the aetiology and prophylaxis of anthrax, including the researches on the dissemination of the disease through the presence of spores in the soil. The following sections recount Pasteur's studies on chicken cholera and attenuation, on vaccinia, variola, plague, peripneumonia, pig typhoid, and cholera. The remarkable series of researches on rabies form the subject-matter of the twelfth section, culminating in the announcement of the successful treatment, by inoculation, of Joseph Meister, aged 9 years, who had been severely bitten by a mad dog. The announcement was made at the Academy on October 26th, 1885, a date which the president rightly described as one of the most memorable in the history of the conquests of science. The remaining sections contain various official documents, including the minutes of the Academy relating to the establishment of the Pasteur Institute. Various scientific notes, lectures, articles and correspondence will form the contents of the final volume, which is in course of preparation.

FUNCTIONAL AFFINITIES OF MAN, MONKEYS, AND APES

Mankind is always interested in his lower relations, and innumerable volumes have been published on the affinities of the human and simian primates. Almost without exception, however, these have been more or less morphological, and it has been left to Dr. S. ZUCKERMAN, in his *Functional Affinities of Man, Monkeys, and Apes*,² to bring within a single cover an authoritative study of the hearings of physiology and behaviour upon the taxonomy and phylogeny of the primates. The interest in the subject is by no means confined to classification, however: the comparative method can be applied to primates as effectively as it can to other animals. What is obscure in a functional activity of man, for example, may be classified by some peculiarity in the working of the homologous process in a related species. Dr. Zuckerman has used the term "functional" in the widest sense to refer to any character revealed by methods used in the investigation of the dynamic, rather than the static, aspects of organisms. He begins with a study of the classification of the order, and proceeds to discuss the differentiation of the mechanisms of reproduction, of blood reactions, of receptor organs and their functions, and of behaviour patterns. He studies the diseases and parasites of the primates, and passes on to consider psychological measure of intelligence in the primates, including a study of the brain, the phylogenetic implication of cortical physiology, and the evolution of primate behaviour. His concluding chapter sums up functional differentiation in relation to the evidence of morphology and palaeontology.

The chapter of most interest in a volume full of interest to the medical man is that dealing with disease and parasites. This subject has only been studied most super-

¹ Œuvres de Pasteur. Tome vi. Deux fascicules. *Maladies Infectieuses, virus-vaccins et prophylaxie de la rage*. Réunies par Pasteur Vallery-Radot. Paris: Masson et Cie. 1933. (Pp. 918 160 fr.)

² *Functional Affinities of Man, Monkeys, and Apes*. By S. Zuckerman, M.A., D.Sc. London: Kegan Paul, Trench, Trubner and Co., Ltd. 1933. (Pp. 203; 24 figures. 10s. 6d. net.)

ficially, and Dr. Zuckerman gives a valuable summary of what is known—especially from the point of view of one concerned with the taxonomic relationships of the primates. The volume is fully illustrated by two dozen excellent representative photographs of various primates. There is also a comprehensive bibliography, both scattered throughout the text and in an appendix, as well as a subject index and an author's index. Dr. Zuckerman's book forms a constructive addition to our knowledge of the comparative physiology and psychology of the order of which man is a member, and it should be of great value to students of the subject.

BREATHING EXERCISES IN PULMONARY TUBERCULOSIS

Writing an official report¹ to the United States Government upon the Hague conference of the International Union against Tuberculosis, Dr. S. ADOLPHUS KNOPF of New York gives an excellent general outline of some phases of contemporary tuberculosis work. The most personal and original is a good description of his method of systematic respiratory exercises in pulmonary patients. The movements are performed in the semi-recumbent position. The stimulus is partly mental (by repeating the suggestion that breath is being taken in from the toes upwards). The object is to change the air at the base of the chest while leaving the upper lobes at rest. It is claimed that by this method, which gives the thoracic muscles much greater repose than during ordinary breathing, healing of active lesions is promoted. In many cases, as the author observes, a patient can make these exercises his only occupational therapy. As a further development of the idea, Dr. Knopf advises elevation of the chest while the diaphragm is in controlled movement. The number of respirations per minute can be reduced greatly. A tranquilisation is achieved which is the very reverse of the deep thoracic respiration that in pulmonary tuberculosis we try to avoid. Probably there is a psychological element in these manoeuvres, and the benefit of such a simple procedure is worth investigation.

Other chapters in this report deal with care work in tuberculosis; psychological and social aspects of after-care work; B.C.G. inoculation; salt-free diet, etc. With regard to Calmette's work and his attenuated bacillus, the author adopts the view of W. H. Park of New York, which is favourable to the method, and he repeats the evidence that has been brought forward as to its harmlessness and efficacy. In this country most workers take a different view on bacteriological and statistical grounds. Dr. Knopf's report is to be looked upon as the personal reaction of a highly competent and experienced observer to some of the problems of his time. And the method of controlled diaphragmatic breathing is one that should be investigated by all clinicians.

"ANNALS OF MEDICAL HISTORY"

The sixth and last of the bi-monthly numbers of Volume v of the new series of the *Annals of Medical History*² bears on its cover the portrait of J. P. Frank, the famous hygienist of the eighteenth century, whose life and work are described by Drs. Leona Baumgartner and Elizabeth Ramsey; their statement that he is now "almost forgotten" is a rather extreme description of the present state of opinion, for his name is written large on

the façade of the London School of Hygiene and Tropical Medicine in Keppel Street. Surgeon-Lieutenant J. J. Kcevil, R.N., gives an account of the work done during his short life of thirty years by William Anderson, master surgeon in the Royal Navy, who sailed with Captain James Cook in the *Resolution*; this article is the result of much research, and is a pious attempt to do justice to the memory of a little-known naturalist. In an informative essay on influenza epidemics Dr. J. F. Townsend recognizes as such outbreaks of disease occurring in 412, 393, and 43 B.C.; full acknowledgement is made to the late F. G. Crookshank, eight out of the twenty references being to his publications. The Graefenberg Medical School, founded in 1851 by Dr. Shepard in Alabama, and conducted as a family concern, is described by Dr. Roy Turner. Under the heading "The Intolerance of Great Men," Dr. D. B. Radner recalls Sir J. Y. Simpson's opposition to Listerism, Pavy's to Claude Bernard's storage of carbohydrates in the liver, Virchow's to Darwinism and to Koch's and Behring's views about toxins and antitoxins, and Pettenkofer's to Koch's cholera work. Sir Humphry Rolleston's interesting article, "The Two Heberdens," is concluded, the portrait of William Heberden, the younger, forming the frontispiece. Dr. Kate Campbell Hurd-Mead's "Introduction to the History of Women in Medicine," which has run through all the six numbers in this volume, also comes to an end, the record reaching the twelfth century. In an editorial, Professor George Dock quotes from a little-known work by J. H. Kopp the information that Larrey had practised mediate auscultation by means of a roll of paper long before Laennec invented the wooden stethoscope.

Notes on Books

Dr. G. E. BEAUMONT and Professor E. C. DODDS show themselves once again as indefatigable as ever in maintaining their popular *Recent Advances in Medicine*³ in an up-to-date condition. In the seventh edition they have added over one hundred pages of fresh material and discarded various sections where methods have not stood the test of time. It is perhaps significant of the trend of medicine that the book now opens with a composite chapter on sex hormones, vitamins, and ductless glands instead of the familiar introductory section on clinical investigation. Other new material deals with such subjects as the urea clearance tests, ketogenic diet, and new work on anaemia, while there is now included a good account of the tests available for estimating respiratory efficiency. To revise each section of the book for each edition must prove a difficult task, but it is surely time that the section on the gastric function should include mention of the use of the alcohol meal and the effects of histamine injection on the gastric secretion. In fairness we must add that attempts to find other deficiencies have failed, and all that is recent and worthy of notice seems to have been included in what must be regarded as one of the most successful numbers of this useful series.

We have received, as a 290-page supplement to the Hungarian publication *Orvosi Hetilap*, a full account of the third session of the Hungarian Medical Week, a yearly gathering of all medical societies of the country, which met in Budapest on June 4th, 1933. Reports were submitted by the Society for Internal Medicine, the Dermatological Society, the Society of Psychiatrists, the National Society of Dental Surgeons, the Association of Oto-laryngologists, the Pediatric Society, the Society for the Study of Rheumatism, the Tuberculosis Society, the Association of Pathologists, the Surgical Society, and the Society of Oculists.

¹ Report to U.S. Government on Tuberculosis, with some Therapeutic and Prophylactic Suggestions. By S. Adolphus Knopf, M.D. New York: National Tuberculosis Association of America, 450, Seventh Avenue.

² *Annals of Medical History*. Vol. V, No. 6, November, 1933. Edited by Francis R. Packard, M.D. New York: Paul B. Heeler, Inc.; London: Baillière, Tindall and Cox. (Pp. 511-612; illustrated. Price for volume of six numbers, £2 15s.)

³ *Recent Advances in Medicine*. By G. E. Beaumont, M.A., D.M., and E. C. Dodds, M.V.O., D.Sc., Ph.D., M.D. Seventh edition. London: J. and A. Churchill, 1934. (Pp. 485; 58 figures. 12s. 6d.)

The second volume of *Brompton Hospital Reports** follows the same lines as its predecessor twelve months ago, containing a group of papers recently published from this hospital, but is considerably improved by the addition of the annual medical report of the institution for 1932, to which is appended a fuller account than usual of interesting cases in the wards during that year. An index to the two volumes is supplied. The present volume opens with two papers of historical interest—namely, a review of the life and times of Nicholas Culpepper by Dr. Cecil Wall, and an appreciation of the influence on medicine of Koch's discovery of the tubercle bacillus, which was prepared by Dr. R. A. Young for the eighteenth annual conference of the National Association for the Prevention of Tuberculosis. The greater part of the book is devoted to papers on the clinical and therapeutic aspects of pulmonary tuberculosis, and in this way a survey is provided of modern views concerning this disease.

Preparations and Appliances

ATTACHMENT FOR SUPRAPUBIC BOX

Mr. H. J. McCURRIE, M.S., F.R.C.S. (Hove, Sussex), writes:

For some time I had been dissatisfied with the rubber belt and attachments for retaining a suprapubic apparatus in position. The belt was apt to become sodden, to perish, and to tear, and in spite of boiling frequently to have an offensive smell. I therefore got the Genito-Urinary Manufacturing Company to make an attachment as shown in the illustration.

On each side of the box there is a pair of rustless steel chains terminating in a buckle. A piece of elastic webbing (which costs for cotton webbing 1s. 6d. a yard, and for silk elastic webbing 2s. 6d. a yard) is passed round the back and buckled to each buckle in front. The webbing is cheap, and when soiled can be thrown away—each case can start with a

new and clean bit. The silk webbing has a more pleasant feeling against the skin. The buckles and chains can be used indefinitely, and are sterilizable by boiling. Another advantage of the chains is that each link is large enough to place on the stud at the side of the suprapubic box, so that an oblique pull can be obtained; for instance, in a very fat patient the chains may be left at full length on the upper studs while several links can be taken up in the lower studs so as to get a pull at right angles to the slope. For a thin concave abdomen this procedure can be reversed.

I prefer a Galbraith's modification of the Hamilton Irving box. It has only one exit tube, and this is situated at the lowest portion of the box, and so a puddle at this point is avoided. In my experience of prostate cases the patients do not lie on their sides while wearing a suprapubic box, and do not desire to do so, so that there is little point in the two tubes. And I believe that the puddle that forms between these two exits is the cause of much of the discomfort associated with a suprapubic apparatus. In the ordinary way while lying quiet a suprapubic box, if the rim is well vaselined, does not leak; some sudden movement dragging on the attachments may lift the box a little, or a sudden inspiration such as occurs before coughing, does this. If there is a puddle the whole of this may escape; if, on the other hand, there is no puddle, and the box is empty, only a drop or two may escape by running down the skin from the wound.

The box is made of rustless steel, and is therefore boilable. These chains have been in use by my colleagues at the Royal Sussex County Hospital and the Brighton Infirmary, as well as by myself, for the last eighteen months, and have proved satisfactory in use. They are supplied by the Genito-Urinary Manufacturing Company, London, W., at 7s. 6d. for a pair of buckles and chains.

KIRSCHNER'S STIRRUP

Major MEURICE SINCLAIR, C.M.G., R.A.M.C. (ret.) (London, W.1), writes:

The figure reproduced here shows a Kirschner's stirrup with a "thread" *in situ*, which has been made for me by Messrs. Down Brothers, Ltd. It has several practical advantages over other stirrups. It is extremely simple in

construction and practical in use. It will also take all gauges of "threads." I have added a quadrilateral "washer" to each end of the stirrup, and through each "washer" an extra hole is drilled—as a holdfast for the extension tapes, which I originally tied to the "thread" between the ends of the stirrup and limb. These holes are seen in the figure, and for practical purposes are situated at the same level as the "thread." This gives an important supplementary value to the stirrup, as it can now be safely used for all fractures of the lower limb. For instance, the "thread" can be passed through the malleoli while the limb is supported in a Thomas splint; the stirrup can be so arranged, and fixed, to be either in front or behind the leg as the surgeon desires. Accordingly, in fractures of the lower limb, with the "thread" and stirrup secured in the above manner, and with the extension tapes fixed to these holes, the stirrup can be used for all the long-bone fractures of the lower limb, and the surgeon can obtain a permanent and efficient pull in the *correct axis* of the limb, while causing a minimum amount of damage for introduction and producing the maximum benefit for the patient—provided the correct aseptic technique has been adopted and the "thread" has been passed through an adequate proportion of bone.

CERVICAL IRRIGATOR

Dr. W. NEVILLE MASCALL, Chief Assistant Medical Officer, L.C.C. Whitechapel Clinic, E.1, writes:

The cervical irrigator here illustrated has been made to my design by Arnold and Sons of 50-52, Wigmore Street, W.1,

and is used at the L.C.C. Whitechapel Clinic, where it has proved very successful in the daily routine treatment of gonorrhoea and other cervical infections.

The instrument is 10 inches long, with a gentle curve to facilitate its introduction into the cervical canal. The gauge along the shaft is that of a No. 8 English catheter. It terminates in a small bulbous protrusion, which is perforated both terminally and on all sides with the gauge of a No. 2 English catheter. This type of construction causes a back-flow which thoroughly douches the vagina.

The instrument is made of stainless metal, and in one to permit easy sterilization.

A CLINICAL AND RADIOLOGICAL EXAMINATION OF WORKERS EXPOSED TO ANTHRACITE DUST

REPORT BY THE INDUSTRIAL PULMONARY DISEASE
COMMITTEE OF THE MEDICAL RESEARCH
COUNCIL.

In 1931 the Medical Research Council referred to their Industrial Pulmonary Disease Committee a request by the Mines Department and the Home Office for an inquiry into whether the working health and capacity of coal miners are impaired by inhalation of anthracite dust, and, if so, to what extent. The Industrial Pulmonary Disease Committee having undertaken to investigate this problem, a preliminary study was made of the size and constitution of the working population at the South Wales anthracite collieries. The results of this study showed that, under the existing industrial conditions, the problem was likely to be an extremely difficult one to solve. To enable an adequate investigation to be made, the basic requirement was a population, of reasonable size, of workers whose state of health—clinical condition, presence or absence of physical impairment, degree of disability, etc.—could clearly be related to the specific factor incriminated—namely, anthracite dust—without the intervention of other extraneous and, possibly, important factors. With underground workers, at the coal face or on the haulage, this requirement was found not to be fulfilled. Such workers are undoubtedly exposed to various concentrations of anthracite dust in the atmosphere they breathe during their hours of work, but they may, in addition, be exposed at times to stone dust containing silica, especially when engaged on such tasks as roof ripping or driving hard headings. It was concluded, therefore, that if underground workers were, in fact, shown to be less healthy than other workers not exposed to anthracite dust, it could not be deduced that their higher rate of disability was due to their exposure to anthracite dust. Their impaired health might equally well be attributed to their exposure to stone dust containing silica, which, it is well recognized, can produce serious damage to health. Since, in addition, the effects of exposure to silica dust will not necessarily be immediately apparent, it was considered essential to reject also any surface worker who had ever worked underground for an appreciable length of time. Again, demonstrable damage to health in such surface workers would not necessarily be due to their exposure to anthracite dust above ground, but quite possibly to their previous exposure to stone dust beneath ground; indeed, already impaired health may have been responsible for their seeking work upon the surface, as is known to be the fact in many cases.

This preliminary survey of the population and its environmental conditions thus led to the conclusion that any consideration of the health of underground workers, past or present, could not contribute to a clean-cut solution of the specific problem. Attention was therefore turned to workers upon the surface. After the coal has been brought to the surface the general procedure at the anthracite collieries is to sort it by mechanical means into various grades according to size. For this purpose it is tipped upon the "screens," crushed, and shaken mechanically on different meshes, so that coal of a given size will fall to its right level and be conveyed on travelling belts either to the washery or direct to the trucks. While the coal is travelling along the belts, operatives are employed to remove pieces of shale, stone, and other foreign matter. Men employed on the processes—tipplers, workers on the belt, and other screen workers—are exposed to the inhalation of varying amounts (sometimes very high) of anthracite dust. In the preliminary survey a census was taken of these operatives at the South Wales anthracite mines, and a study was made of their age distribution and length of employment upon these and other operations. It was found, without doubt, that there was a decided tendency to draft to

this relatively light work numbers of operatives who had previously worked underground and had for one reason or another become partially incapacitated or damaged lives. In addition, this preliminary inquiry showed that a large number of boys start work upon the screens but rapidly move away to other employment. The general evidence was that they are drafted underground, where the physical labour is heavier but the rate of pay superior. The inference must be that the healthiest and strongest workers will inevitably transfer to underground work, and it follows, therefore, that the screen workers, *apart from their recruitment of the disabled in later life*, are at all ages likely to include an undue proportion of men of under-average physique and health.

If, then, the examination of such a group of workers should show that it included a high proportion with impaired health, or that it suffered an unduly high rate of sickness, this result alone could not with any adequate degree of certainty be ascribed specifically to the effects of the inhalation of anthracite dust. It might be considerably influenced by the fact that the workers who select screen work and remain upon screen work are initially less healthy than any control group of surface workers adopted for comparison; in other words, any difference in health apparent might be the expression of the reaction of under-average lives to such general factors as tuberculosis, fibrosis, etc., rather than the reaction of normal lives to exposure to anthracite dust. Only the finding of some distinctive form of impairment that does not occur in persons unexposed to anthracite dust could remove this objection. In the absence, as yet, of any evidence suggesting that such a distinctive form of disability would be present, it was felt that no group of workers at the mines, either on the surface or below ground, could provide material by which the solution of the problem could satisfactorily be determined.

It therefore became necessary to see whether any other group of workers could supply the essential requirements of the investigation. For this purpose a preliminary survey was made of coal trimmers at Swansea docks. These workers are engaged in the hold of a ship during loading operations, their task being to level the coal as it is shot into the hold by mechanical conveyors. Their work is heavy, so that the recruitment of the physically unfit for the job is improbable, and this factor was therefore not likely to be of importance. They are exposed to the inhalation of anthracite dust, but also to other coal dusts, as the same workers will load any kind of coal according to the supply of the various kinds at different ports. The greater part of the anthracite supplies are loaded at Swansea, and here it forms a very large percentage of the total coal loaded; attention was therefore confined to the trimmers at this port. Their number is not large, roughly 250, and a study of the sickness or total disability rate of such a small group would not be illuminating. Accordingly, it was decided that the most hopeful line of approach would lie in the clinical and radiological examination of a sample of these workers. If the results of such inquiry revealed the presence of any distinctive form of disability the problem could then, it was felt, be reopened at the mines with more hopes of success.

It was determined to examine a sample of forty operatives, or, roughly, one-sixth of the total, the sample to comprise a group of fifteen recruits to the industry, whose employment in coal trimming amounted to three to four years, and a group of twenty-five older men with fifteen to forty years' service. These two groups were chosen at random from the complete list of operatives, with the intent that the first group should give a representative picture of the type of operative recruited by the occupation, and the second group a representative picture of men who had been at work for a relatively long period of time in the environment. The selection was completed in the third week of June, 1933, and when the examinations were commenced, on July 10th, eleven of the selected men were absent (one dead, two ill, eight for unknown reasons). Four of these absentees were from the group of "recruits," and seven from the group of

older workers. To make good the deficiency in numbers, volunteers were secured from the docks in place of the absentees. Such substitutions make it doubtful whether the sample is completely representative of the whole population. The results of the examinations may have been affected, it seems, by a readiness to volunteer on the part of individuals, who, on account of some known or suspected disability, desired to be examined. In the list of results of examinations the "volunteers" are numbered 41 to 51, and the gaps in the serial numbers 1 to 40 indicate the absentees for whom they were substituted. By arrangement with the Home Office, the clinical examinations were made at Swansea by two members of the Silicosis Medical Board. The record of examination of each worker included the following data: age; duration of employment in coal trimming; nature and duration of work in any other employment; family and personal history of illness; notes on general nutrition, the presence of respiratory embarrassment, cough, expectoration. Measurements of the chest and the condition of the upper respiratory passages were noted. A complete clinical examination was made, in which physical signs were recorded and interpretation of the clinical findings noted in each case. The condition of other organs was noted, and, finally, the degree of impairment of general physical capacity, if any, was estimated. The Welsh National Memorial Association, through its chief medical officer, undertook the radiological examination at the Swansea Tuberculosis Institute. These radiograms were examined in London by a special subcommittee of the Committee on Industrial Pulmonary Disease on July 21st, 1933, and the members independently recorded their interpretations of the films.

The Medical Board's records of the clinical examinations and the findings of the subcommittee on radiograms were carefully studied by the whole committee, and the results of its conclusions are set out in the table below. In this table particulars of the employment, history, and the personal history of illness are given for each person examined. The conclusions arrived at in the interpretation of the clinical and radiological data are indicated for each case by the letters A, B, C, and D, which have the following significance:—A: Nothing in the examination to suggest fibrosis in the lungs (nineteen cases). B: Evidence of fibrosis in the lungs not considered to be due to dust but to other causes, mainly antecedent disease (fourteen cases, of which nine are among the "volunteers"). C: Some clinical evidence of fibrosis in the lungs not confirmed radiologically (two cases). D: Pathological conditions found in the chest other than pulmonary fibrosis and not due to dust (five cases).

The personal history of previous illness includes five cases of influenza occurring within the last two years; six of pneumonia, two of these during Army service, and four during the period of work on coal trimming; three cases of pleurisy, all during the period; and three cases of rheumatism, two of them before the period. Pulmonary tuberculosis was diagnosed in four cases definitely, in three of which the disease appeared to be old and inactive; in three other cases the presence of the disease was suspected.

After considering the reports provided by the clinical examiners, the committee was unable to find, in this series of cases, any evidence that the inhalation of anthracite or other coal dust had caused fibrosis of the lungs.

The thanks of the committee are due to Drs. Keating and Thomas for carrying out the clinical examinations, and to Drs. Howell Williams and Prosser Evans for conducting the radiological examinations. Without the active co-operation of employers and trades union officials it would not have been possible to make adequate arrangements for the inquiry, and the committee wishes to thank representatives of the Amalgamated Anthracite Collieries and other employers; Mr. J. James, secretary of the Anthracite Miners' Branch of the South Wales Miners' Federation, and other trades union officials; Mr. Jonah Charles, district secretary of the Transport and General Workers' Union; and Mr. H. W. Morgan, representing the Great Western Railway Docks at

Swansea. All of these either co-operated in the preliminary inquiries at the mines or facilitated the arrangements for examining the coal trimmers.

TABLE SHOWING RESULTS OF EXAMINATION

No.	Age	Period of Employment in Years					History of Past Illness	Classification
		Coal Trimming	Other Coal Dust	Underground	Other Dusty Occupations	Non-dusty Occupations

The members of the Industrial Pulmonary Disease Committee appointed by the Medical Research Council are: Professor A. J. Hall, M.D., F.R.C.P. (*Chairman*); A. E. Barclay, O.B.E., M.D.; J. C. Bridge, F.R.C.S. Ed.; Professor S. L. Cummins, C.B., C.M.G., M.D.; Professor E. H. Kettle, M.D., F.R.C.P.; Stanley Melville, M.D.; Air Vice-Marshal Sir David Munro, K.C.B., M.B.; Professor M. J. Stewart, M.B., F.R.C.P.; Cecil Wall, D.M., F.R.C.P.; and E. L. Middleton, M.D. (*Secretary*).

British Medical Journal

SATURDAY, FEBRUARY 3rd, 1934

THE CARE OF CHRONIC ILLNESS

The institutional accommodation required for people suffering from chronic diseases differs in a number of respects from that needed for cases of acute illness. At the present time, when economy is still imperative and local authorities are completing their survey of hospital and other institutional provision for all those for whose care they are responsible, it is important to ascertain as nearly as may be not merely the total amount of the accommodation needed, but also, since this must vary in kind, the proportion of each kind which it will be wise to supply. On November 11th last (p. 879), under the title "Chronic Disease and the Community," we considered the general question of the need for communal care, and referred to the statistical and other conclusions which had been arrived at in a report on chronic illness in New York by Mary C. Jarrett, published on behalf of the Welfare Council of that city. The second volume¹ of that report, and part of the first volume, are devoted to a consideration of the institutional provision, both municipal and private, there needed and available. While the main conclusion arrived at is that the accommodation existing to-day is very deficient, both in amount and in character, it is possible that some of the facts set out may have a bearing upon the situation in this country. Here, as in New York, it may be found that "discrepancies between the type of care best suited to the patients' needs and the type of care they receive indicate that, in addition to the insufficiency and inadequacy of facilities for the chronic sick, there is also considerable misuse of the existing facilities."

The reader must bear in mind that in the New York report cases of pulmonary tuberculosis, mental disease, and blindness and deafness are not considered, public provision being already available for these classes. Apart from this, approximately 1 per cent. of the population is said to be disabled by chronic disease. We find it a little difficult from the various figures given to gather what exact proportion of these sufferers is regarded as needing institutional care of one kind or another, but it seems to be rather more than a half. The rest may be adequately dealt with by care at home, or by a clinic or dispensary. Three grades of institutional care can be distinguished. To adopt the nomenclature of the report, there are: first, medical care (A), for those who need active medical study and treatment; secondly, nursing care (B), for those who require skilled nursing under medical supervision; thirdly, attendant care (C), for those who are disabled and need assistance but cannot be further benefited

by medical treatment. For the first two types some form of hospital is required; for the third type an institution mainly of a custodial character suffices. Of the total number of patients covered by the New York census about 20 per cent. are regarded as being in need of institutional provision of the A type; about 3 per cent. of the B type, and about 34 per cent. of the C type. This calculation is, however, complicated by another consideration. Cases of chronic illness may obviously be classified, not according to the degree of medical and nursing attention they need, but according to the nature of the disease itself; and so it may be desirable or convenient to provide institutions for the care of orthopaedic cases, of neurological cases, of cardiac cases, of rheumatic cases, or of cancer cases, of varying degrees of severity.

Provided that these hospital beds for chronic illness, whether of a special or of a more general character, are made freely available for purposes of teaching and of clinical research, it may be held to be inadvisable to admit cases of chronic illness into the wards of general hospitals primarily intended for more acute cases. Such cases, medical and surgical, are likely at any time to be numerous enough to occupy all the beds available for them. They produce and require an "atmosphere" quite different from that most suitable for more chronic cases; and the medical and surgical staffs, and sometimes the nursing staff also, are apt to regard the presence of chronically ill patients as preventing the admission of cases of a more interesting and hopeful kind, and as producing a feeling of helplessness in dealing with "chronics" in the absence of social and economic adjustments which lie outside the medical province. Nevertheless, from one cause or another, there will usually be a certain number of cases of chronic illness in the ordinary general hospital. At the time of the New York investigation some 20 per cent. of the accommodation of the hospitals primarily intended for acute illness was occupied by such patients. The investigators regarded four-fifths of these as being out of place, and express the opinion that from 3 to 5 per cent. of the beds in general hospitals are really required for patients with chronic illness admitted for what they regard as legitimate reasons. These grounds are: emergency admission, temporary observation for a special condition, and the need for receiving treatment for an acute phase of the chronic illness. Clearly, institutions for chronic disease of the C type mentioned above should always be in close touch either with a hospital of the A type or with a general hospital.

It must not be assumed that all hospitals or institutions for the reception of cases of chronic disease can be established and maintained at a less cost than the ordinary general hospital. For the most part, and on the average, this will be true; but hospitals of the A type may require almost as complete a medical and surgical equipment as the general hospital, and many of them, as well as institutions of types B and C, need, in addition, provision for purposes of recreation and outdoor exercise which the hospital for acute cases is not expected to have. Moreover, the much greater

¹ *Chronic Illness in New York City. Vol. II, The Care of the Chronic Sick by Different Types of Voluntary Agencies.* By M. C. Jarrett. London: H. Miltch, Oxford University Press, 1933 (2 vols., not the two volumes).

importance and extent of various social services and agencies in connexion with hospitals and institutions for chronic illness, and the entirely additional need for educational service, especially in hospitals for children suffering from rheumatic, cardiac, or orthopaedic conditions, have to be reckoned with. These last are, however, merely services transferred to the hospital from another sphere in which they would be wanted in any event. In the New York report there is an excellent chapter explaining and describing "medical social service in relation to the care of the chronic sick." We commend this to the perusal of any member of a hospital staff who is not already convinced of the paramount need for this kind of work and co-operation.

PITUITARY TUMOURS

As a result of a study of tumours of the pituitary gland recently met with at their hospital in Paris, Roussy and Oberling¹ present an interesting account of the types of tumour occurring in this region. Coming from so important an authority in this domain as Roussy it will be of interest to examine shortly the views he puts forward. Glandular tumours of the pituitary, he says, belong for the most part to the adenomata, and their histological study raises two problems. First, we wish to know the nature of their constituent cells, since the clinical manifestations of the tumour depend upon this. Secondly, it should be possible to determine the degree of malignancy of the tumour removed surgically, and thus decide on the necessity for accessory treatment.

Pituitary adenomata are relatively frequent, 10 per cent. of all subjects showing adenomatous foci, although in the vast majority of cases these foci are microscopic in size. The authors consider that these minute foci are able to give rise to real pituitary tumours as a result of as yet unknown stimuli to proliferation. Pituitary adenomata are seen at all ages, but mostly in young adults of either sex. The constituent cells of these tumours resemble one or other of the cells of the pituitary gland itself. The cells are either chromophobe—with poorly developed protoplasm, poorly staining, and non-glandular—or chromophil, with highly developed cytoplasm containing easily stainable granules (eosinophil or basophil). It was Roussy and Clunet who applied the terminology at present commonly used to these tumours—namely, chromophobe and chromophil adenomata. Later the chromophobe tumours were divided into trabecular and alveolar types, and it came to be recognized that the chromophil tumours differed from the chromophobe, not only by the presence of granules, but also by the different character of the nucleus and the volume of the cytoplasm. Adenomata have also been described the cells of which resemble in greater or less degree both the chromophobe and the chromophil cells (Dott and Bailey). The existence of tumours in association with pregnancy, which consist apparently of the hypertrophied principal cells of the

pituitary, is considered and confirmed by the authors. Since the diagnosis of the nature of the pituitary tumours is still a matter of histological technique, the authors emphasize the necessity for the employment of only the best methods and reagents.

The great majority of pituitary adenomata are of the chromophobe type, in that they are agranulocytic, but their cytoplasm may be in considerable degree chromophil, so Roussy and Oberling prefer the term "agranulocytic adenoma," reserving the term "chromophobe" for the cells with clear cytoplasm only very lightly stainable with eosin. In general these tumours are very vascular. In a consideration of tumours with eosinophil but non-granular cells (pregnancy cells) it is suggested that they present evidence of a gradation from the parent true chromophobe to the eosinophil chromophil cell. Of the basophil adenomata the authors have nothing to add to the classical description, but state that they may easily be missed on a first examination. As to the eosinophil adenomata it is pointed out that the cells differ widely in their content of granules, some being crammed and others entirely free from them. Some present the appearance of having discharged their granules and remain vacuolated. Roussy and Oberling confirm the observations of other workers in stating that these chromophil tumours of the pituitary are never mixed in the sense of containing both eosinophil and basophil cells. Tumours of intermediate type between chromophobe and chromophil are, however, found, and others consisting of a mixture of chromophil and chromophobe cells are also described.

Attention is drawn to the secondary lesions to which pituitary tumours are liable, especially haemorrhages with subsequent formation of areas of necrosis. Whilst adducing evidence that the chromophobe tumours are the most frequent, Roussy and Oberling advise caution in interpreting statistics. As regards the malignancy of pituitary tumours it is considered certain that they vary widely in this respect, some remaining stationary for years, others showing signs of rapid extension and invasion. The histological classification of these "malignant" tumours is still unsettled.

AETIOLOGICAL AGENT IN MUMPS

C. D. Johnson and E. W. Goodpasture¹ have lately recorded experiments in which they were successful in producing acute non-suppurative parotitis in monkeys by inoculation with saliva taken from early cases of mumps. Of six specimens of saliva collected from patients and inoculated directly into Stensen's duct in *rhesus* monkeys, four proved virulent. The clinical course, with its incubation period, its rise of temperature, its leucopenia with relative lymphocytosis and often true monocytosis, and its painful enlargement and oedema of the parotid glands, closely simulated the disease in man. Macroscopically, glands removed from monkeys that were killed were markedly congested, and revealed small haemorrhagic areas varying

¹ *Presse Médicale*, November 15th, 1933.

¹ *Journ. Exper. Med.*, January, 1934, p. 1

from pin-point up to 1 to 2 mm. in diameter, while sections showed primary degeneration and necrosis of single or small groups of acini accompanied by diffuse oedema. Passage experiments were successful when a suspension made from the ground-up glands was injected into Stensen's duct on both sides. Altogether seven passages have been made without any apparent diminution in the virulence of the infective material. Ground-up glands from monkeys filtered through a Berkefeld N candle proved to be virulent in each of five trials. The authors have satisfied themselves that the lesions are not the result of ordinary bacteria or of spirochaetes, and are not determined by either the vaccinia or the herpes virus. They consider that the disease they have produced is a specific parotitis due to the same agent—a filterable virus—as is responsible for mumps in human beings. Experiments show that the virus is resistant to freezing, to desiccation, and to 50 per cent. glycerin. It has not yet been shown to give rise to special inclusion bodies, and attempts to neutralize it with the sera of immune persons have not yielded very clear-cut results. (The paper contains convincing illustrations of monkeys suffering from parotitis.)

MEDICAL MEN CALLED "SYLVIVS"

"Wood" is not an uncommon name in this country, and in the sixteenth and seventeenth centuries medical men with its equivalents—"Dubois" in French, or in its latinized form "Sylvius"—were not unknown. Thus the *Dictionnaire des sciences médicales, Biographie médicale* (1820) gives short notices of four bearers of the name Dubois otherwise unknown to fame. Two others very familiar in medical history under the name of Sylvius are the physiological chemist of Leyden, François de la Boë (1614-72), and the anatomist of Paris, Jacques Dubois (1478-1555), teacher of Vesalius and later, as a bigoted follower of Galen, his opponent. These two prominent men are often confused, and there is another medical man, probably of English descent, who is sometimes called Sylvius—namely, Zachariah Wood, "Physician of Rotterdam," who translated into Latin the *Dissertation* (1653) of Jacobus de Back of Rotterdam, and into English the *Exercitationes anatomicae de Motu Cordis et Sanguinis Circulatione*. His preface to the latter work expressed the position about Harvey as the discoverer of the circulation (thus challenging the sacrosanct doctrine of Galen, which had dominated medicine for more than thirteen centuries) in the words: "Truly a bold man indeed, O Disturber of the quiet of physicians, O seditious citizen of the Physical Commonwealth." It would be interesting to know more about Zachariah Wood. In a communication to the Bibliographical Society of Ireland Dr. T. Percy Kirkpatrick,¹ the historian of Irish medicine, has recently unearthed, and given an account of, another Jacobus Sylvius (1646-89), who in 1686 published in Dublin a thin octavo volume entitled *Novissima Idea de Febris*. This went through five editions, the last in 1700, which are exhaustively analysed from a bibliographical point of view by Dr. Kirkpatrick. It was a mechanical explanation of fever

based on faulty physiology and inadequate pathology, and, though containing evidence of observation, is mainly of historical interest in anticipating many of the iatro-mechanistic views of the versatile Friedrich Hoffmann (1660-1742) in later times. It strongly recommended the therapeutic use of camphor, as Hoffmann did in the treatment on much the same grounds early in the next century. This Jacobus Sylvius described himself as a Hollander, and as having entered on the physic line at Leyden on January 18th, 1666-7; he appears to have come from Dordrecht, but when and where he obtained the doctorate, or exactly when he came to practise in Dublin, where he died intestate in 1689, is unknown. There is not any proof that he is related to the great Sylvius of Leyden. He was an original member of the Dublin Philosophical Society founded in 1684 by Sir William Petty, and in the dedication of his book to William Stuart, Viscount Mountjoy, and to the members of the Dublin Philosophical Society he apologizes for his silence in the society for more than three years, and explains it as partly due to modesty and partly to ignorance of the English language. Why in these circumstances he came to practise in Dublin is unexplained. He used the microscope and examined the blood and the semen, but though he wrote of "insensible particles" apparently in solution in the former, he did not see the red blood corpuscles or refer to Malpighi or Leeuwenhoek's accounts of them in 1661 and 1674; in the human semen he described infinitely small animalcula, but again did not mention Leeuwenhoek's previous observation.

THE PSYCHO-GALVANIC REFLEX

Nearly half a century ago the phenomenon known as the psycho-galvanic reflex was first described by a French worker, Féré, and since then others have confirmed the existence of the reflex and investigated the physiology and psychology of its production. The reflex consists of a fall in the electrical resistance of the skin during mental effort or emotion. This can be recorded by passing a low-tension current through the skin of a hand connected with one branch of a Wheatstone's bridge, certain constant conditions being maintained during the experiment and a suitable galvanometer being used for indicating electrical variations in the circuit. Electrodes of silver coated with silver chloride are the only kind found to be reliable for this procedure. The first workers attributed the reflex to changes in the peripheral blood vessels, but this theory was shaken by Varaguth, who concluded that the response was due to increased activity in the sweat glands, which thereby lowered the skin resistance. Varaguth's theory received more support than any other, but recent work fails to find any real evidence for assuming that the sweat glands are concerned. Indeed, when sweating was abolished by the action of atropine the response still occurred, and also was elicited in a patient in whom sweat glands were absent (confirmed by histological examination). In 1924 Aveling and McDowall, working on chloralosed and decerebrate cats, established the primitive nature of the reflex and found that the electrical resistance of the skin was lowered by conditions causing vaso-

¹ Kirkpatrick, T. P. C.: *Irish Journ. Med. Sci.*, December, 1933, p. 67.

constriction in the skin, and was raised by conditions causing vaso-dilatation. Subsequently Wells developed this work on man, confirming the findings that the electrical response was increased by vaso-constriction and diminished by vaso-dilatation in the skin. Among conditions causing the former are cold, injection of adrenaline, and haemorrhage, and the fall in electrical resistance during the menstrual period is probably due to the last. In a recent survey¹ of the physiology of the psycho-galvanic reflex, McDowall, by accounts of his own and other experiments, shows that the reflex is influenced by the circulation in that part of the skin in the electrical circuit, and that when the response is elicited vaso-constriction is always observed. The work of Lewis and Zotterman (1927) goes to prove that the reflex is produced in the stratum corneum of the skin. Its biological significance is still obscure, but evidence points to its being possibly of a protective nature, arising from primitive sensory stimulation and producing in the body a state of alertness in preparation for defence or attack. There is, however, another possible application of the psycho-galvanic response that deserves investigation. As long ago as 1893 Head² demonstrated that, in certain diseased conditions of the viscera, well-defined areas of skin became hyperalgesic. These findings are still used to-day by surgeons by the inaccurate and clumsy method of pinching the skin or testing it with the point of a pin. The areas so defined must therefore be in a physiologically abnormal state, and it should, in view of all the recent developments in our electrical knowledge, be possible to indicate this by appropriate apparatus. It would indeed be a useful clinical development of the psycho-galvanic reflex if it were shown that a skin "patho-galvanic reflex" existed which could be measured, and from this some idea might be gained of the activity of the morbid state of the viscera corresponding to each particular area of skin as established by Head. Here, then, is an opportunity for the experimental physiologist to prove or disprove the existence of such a reflex—not, indeed, a physiologist working in a laboratory, with laboratory animals and apparatus, but one with medical training who would carry his researches to the bedside of pre-operative cases and check his results by the findings in the operating theatre.

HYPERVITAMINOSIS A

The artificial production of vitamin D by irradiation of ergosterol was soon followed by the discovery that excessive doses of irradiated ergosterol caused toxic effects. It was suggested that these were due to some toxic by-product. This hypothesis was abandoned when it was found that the same results were brought about by excessive doses of pure calciferol, but recent investigations have shown that irradiation of ergosterol produces a series of activated sterols, and that some of these are more toxic than others. Hence the original hypothesis of a toxic by-product appears to have been approximately correct in the case of hypervitaminosis D. When it was found that vitamin A was formed in the body from carotene, and when its chemical nature was consequently determined, the preparation of pure con-

centrates of this vitamin was facilitated. Experiments with these have indicated that gross excess of vitamin A leads to toxic effects. Agduhr³ in 1928 drew attention to certain toxic consequences of cod-liver oil, while Drigalski² described toxic symptoms in rats induced by pure vitamin A. The chief symptoms were loss of weight, loss of hair, and inflammation of the eyes. This work has been confirmed by Collazo and Rodriguez,³ who gave young rats a daily dose of 20,000 rat units of a preparation of pure vitamin A. Beyond the observations already mentioned these latter workers also found exophthalmos and fragility of bones, the latter resulting in spontaneous fractures. These findings have a certain resemblance to the Schuller-Christian syndrome, a pathological condition occasionally observed in human patients, which is said to be associated with hypercholesterinaemia. The authors state that in their animals they demonstrated a disturbance of the cholesterol metabolism and a marked cholesterol impregnation of the reticulo-endothelial system. In conclusion, it may be pointed out that these experiments do not suggest that there is any practical danger associated with the clinical use of vitamin A, since the doses given were so enormous.

OPHTHALMOLOGY IN EGYPT

The seventh annual report of the Giza Memorial Ophthalmic Laboratory⁴ in Cairo, of which Dr. Rowland P. Wilson is the director, contains many records of interest. Ocular tuberculosis, it is observed, is very rare in Egypt, although the mortality from all forms of tuberculosis is higher in Egypt than it is in America. Angelucci and Sgrosso have suggested that there is a natural opposition between tuberculosis and trachoma; the former thought a serum from trachomatous patients effective in ocular tuberculosis. In a recent examination of 240 tuberculous patients all were found affected by trachoma, but none showed any ocular tuberculosis. In diseases of the retina it is recorded that myopia and its sequelae play a most important part; high myopia is frequently seen in Egypt. As might be expected detachment is not uncommon; in 1931 it accounted for 31 per cent. of all diseases of the retina. Myopia is prevalent amongst Egyptians; this is all the more striking since most of the people are illiterate. Meyerof said: "It appears to me incontestable that the Egyptian race is particularly subject to hereditary weakness of the posterior sclerotic, which, as it yields, gives rise to myopia. Heredity in the myopia of Egyptians is certain." An interesting experiment in preventive treatment of trachoma and conjunctivitis has been carried out in a village for three years. "Blue drops" (zinc sulphate 0.5 per cent. with mercury pyocyanate 0.01 per cent.) and droppers were supplied to every household and a trained nurse gave instructions to the mothers. At first there was enthusiasm, then slackness, and the venture failed. Next the experiment was tried on children whose parents wanted them to have good eyes, but this also failed. The chosen babies were visited

⁶ *Schindler's Press, Cairo, 1933.*

at their homes, but it was found that, after a time, the children had been removed. In the end, bribery was resorted to. Ten babies were selected. Five received trypanflavine drops regularly, but all developed trachoma; the other five had "blue drops," and only one developed trachoma after nine months; the others remained free after one year. This is held to be remarkable, considering the state of the village and the fact that the average onset of trachoma is at six months. The results of a number of new methods of treating trachoma are given. Chaulmoogra oil combined with copper sulphate was of value. Hydnoceol and copper sulphate acted similarly to chaulmoogra oil, but had a little advantage where there was discharge. Antimony compounds were useless. Certain vaccines had been advocated but were found of no service. Heat treatment of the pannus showed some advantage, but conjunctival lesions did not benefit. There is a valuable paper on a research conducted by Major F. H. Stewart on the Prowazek-Halberstaedter body found as an inclusion in the epithelial cells of the conjunctiva. These "bodies" were discovered twenty-five years ago in trachoma, and despite much arduous research their true role is unknown. Major Stewart has been unable to find them in a single case of uncomplicated trachoma. He comes to the conclusion that trachoma without inclusion "bodies" may be the pure disease, and trachoma with inclusions a secondarily infected form, in which case the bodies are the result of the secondary infection and not the cause of the condition. He thinks that the "body is formed by the phagocytosis of bacteria which are not the cause of trachoma but which may carry the virus of that disease." The report is well illustrated.

LATE CONGENITAL SYPHILIS

A valuable contribution¹ to the subject of congenital syphilis, by Dr. F. R. Smith, is interesting in the light shed upon the late clinical manifestations and the treatment of this malady in its late stages. The material consisted of 462 patients seen in the syphilis clinic of the Johns Hopkins Hospital; all were over 13 years of age. In not a single instance in the series had the mother been treated for syphilis during pregnancy, since, as Dr. Smith remarks, the mean age of the patients was 15 years and "the routine treatment of pregnant syphilitic women was not current practice when these patients were *in utero*." In histories obtained from the parents the evidence of manifestations of infantile syphilis was completely lacking in nearly 90 per cent. In 195 of the patients the infection was latent, while in the remainder by far the commonest sequelae were disease of the eyes, osseous lesions, nerve deafness, disorders of the central nervous system, and other lesions, in that order of frequency. The blood Wassermann reaction was positive in 92 per cent. of the cases, and in the 182 patients who were free from any clinical evidence of involvement of the nervous system examination of the cerebro-spinal fluid showed asymptomatic neurosyphilis in 10 per cent. Details of therapeutic results have been analysed for 267 of patients in this series. The method employed has

usually been arsphenamine alternating with a heavy metal. Before 1925 the metal usually given was mercury by inunction, but since that date this has been abandoned in favour of intramuscular injections of bismuth salicylate in oil. These drugs have been administered by a continuous method, the arsenical preparation for a course of six to eight weekly injections alternating with the heavy metal course of six to twelve weeks. The treatment has been considered "adequate" when fifty or more weeks of therapy have been possible, "moderate" when between thirty and fifty weeks, and "inadequate" when less than thirty. The results of treatment have been estimated mainly from the clinical aspect, "satisfactory" meaning that the patient has been restored to physical health and maintained in this condition for an indefinite period of time irrespective of whether the Wassermann reaction became negative or not. On this basis some rather surprising results were obtained, for over 80 per cent. of the patients receiving "inadequate" treatment had a satisfactory clinical outcome, a proportion slightly higher than the patients receiving "moderate" or "adequate" treatment. Relapse or progression in the symptoms appeared in about 20 per cent. of the entire group; this was unrelated to the length of treatment. A persistently positive Wassermann reaction was as common in patients treated for a year or more as in those treated for six months or less, and Dr. Smith does not consider failure to reverse the Wassermann reaction as of unfavourable prognostic significance. Various other aspects of the problem are dealt with in his review. For example, so-called "nerve deafness" occurring in sixty-two patients in the present series was not associated with signs of disease of the nervous system in a single instance, and Dr. Smith considers that the evidence means that, whatever the nature of the lesion in such cases, it is outside the nervous system. Treatment in the latent cases was extremely effectual in preventing the subsequent development of the serious eye and ear complications, but a little treatment appeared to do just as much as a great deal. The final conclusions, which appear of great importance, are that the optimum amount of treatment varies according to the disappearance of the clinical features of the malady, and that the blood Wassermann reaction may be completely disregarded as a guide to the type of treatment or to its duration.

SIR WILLIAM HARDY

Sir William Hardy, F.R.S., the distinguished biologist who died on January 23rd, soon after coming into office as President of the British Association, had many close contacts with medicine, though, unlike most of the Cambridge physiologists of his time, he did not take a medical degree. Richly endowed with the qualities of mind and heart that inspire confidence, he soon made his mark in the scientific life of the university, both as investigator and as teacher. Later years brought him opportunities to develop a great gift for scientific organization, and for the application of laboratory work to the needs of everyday life. As joint secretary of the Royal Society he proved a far-seeing friend to research in pure science; and

¹ *Bull. Johns Hopkins Hosp.*, 1933, *lun.* 231.

when problems of war rationing arose he threw himself into a new branch of applied science, first as secretary to the Food (War) Committee of the Royal Society, then as chairman of the Food Investigation Board, and latterly as Director of Food Investigation under the Department of Scientific and Industrial Research and head of the Low Temperature Research Station at Cambridge. The country and the Empire owe an incalculable debt to Hardy for the work done under his leadership during the past eighteen years in a hitherto almost untilled field. It is not too much to say that the outcome of these investigations into the scientific problems concerned with storage and transport of foodstuffs is revolutionizing the food industry. In former years, when university lecturer in physiology, he taught and inspired a long line of students who have passed on to work in various branches of medicine. Many Cambridge men who later won distinction in medical research or practice are indebted to him and to Sir Hugh Anderson, M.D., F.R.S. (also a Fellow of Gonville and Caius, and afterwards its Master), for their first clear ideas of method and sincerity in scientific work. Hardy and Anderson were fast friends, complementary the one to the other in temperament as in physical stature, and Hardy wrote for these columns a beautiful tribute to the Master of Caius at his death in 1928. Both were benefactors to medicine and to innumerable members of our profession.

STANDARDIZATION OF BIOLOGICAL STAINS

In view of the importance of stains and staining materials used by microscopists engaged in biological investigation and research, and with a view to mitigating the variability of stains at present available, the Council of the Royal Microscopical Society announced at its annual general meeting, on January 17th, the appointment of a committee to consider the standardization of biological stains and staining materials manufactured in this country, and to make recommendations to the council of the Society of standard specifications and tests for adoption, with a view to the certifying of manufactured stains conforming to such standards. In addition to those Fellows of the Society appointed by the council to serve on the committee, the following official bodies have appointed representatives to serve thereon: the Medical Research Council, the Royal Society of Tropical Medicine and Hygiene, the Institute of Chemistry, the Chemical Society, the Society of Chemical Industry, the Pathological Society, and the Physiological Society. The committee has held several meetings during the session covered by its annual report, and the drafting of standard specifications for methylene-blue, acid fuchsin, and eosin are under consideration. In addition, a standard specification for xylol for microscopical purposes is receiving attention. Other stains will be dealt with as soon as the biological tests of those in hand have proved them to be satisfactory. It is felt that with this organized co-operation between chemists and biologists, manufacturers of British stains will welcome the results of the committee's deliberations.

The sixty-fifth annual meeting of the Canadian Medical Association will be held at Calgary, Southern Alberta, from June 18th to 22nd.

SCIENCE AND INDUSTRY

PROGRESS OF ORGANIZED RESEARCH

During the year 1932-3, reviewed in the annual report of the Department of Scientific and Industrial Research,¹ the grant of £1,000,000 made by the Government in 1917, for the encouragement of industrial research, became exhausted. The fund has been used by the Department for assisting the formation of co-operative research associations in various industries, maintained partly by grants from the Department and partly by subscriptions from industry. Though the "million fund" is no longer available the Department's grants are now being made from its Parliamentary Vote. A large part of the report of the Advisory Council of the Department, signed by Lord Rutherford, is devoted to a survey of the research association scheme and to summarizing the results of this important experiment. The expending of the million fund has attracted a total industrial contribution of £1,750,000, and at the moment the State is contributing £65,000 a year and industry £170,000 a year towards the support of a group of nineteen research associations, which include in their membership some 5,000 firms.

While it is impossible, as a rule, to assess in terms of money the important part played by the research associations in the industrial progress of the country, nevertheless some very striking examples are quoted to illustrate the enormous savings that have accrued from research work in various large industries. An annual sum of less than £250,000 is trivial, the report continues, in relation to the interests involved and the possibilities awaiting realization. The basis on which many of the research associations are working is hardly commensurate with the size of the industries they serve.

DOMESTIC APPLICATIONS

Much of the work in progress at the Department's own establishments and in the laboratories of research associations is of direct interest to every householder and housewife. For example, work in progress at the Department's Building Research Station includes the study of the most economical means of warming a house, investigations on wall plasters, on the problem of damp walls, on painting on cement and plaster, and on the deterioration of bricks. A full investigation is being carried out on the factors causing the frost bursting of water-pipes of various materials; while means are being found for the prevention of the corrosion of galvanized hot-water tanks and of the dulling of the bright metal surfaces used architecturally both inside and outside buildings.

The work of the Food Investigation Board of the Department is meeting with considerable success in improving the quality of foodstuffs and in eliminating waste by better methods of transport and storage. In this connexion a study of the storage of bacon in carbon dioxide promises to be of real assistance to bacon curers in this country, while improved kilns for the smoke-curing of fish, based on methods of control worked out at the Torry Research Station, have been erected by commercial firms.

The Wool Industries Research Association has found a new process for making wool unshrinkable by the treatment of the wool fibres in bulk before they are spun. The process also eliminates, it is claimed, the usual prickly feeling met with in woollen goods, and gives lustre and softer handle to the fabrics. The work of the Association has also provided the public and manufacturers with reliable scientific tests for judging the resistance of a coloured woollen fabric to fading as a result of impurities in the atmosphere, dampness, or laundering. Tests for shrinkability have also been devised. Again, the Cotton Research Association has evolved a new method for the rapid separating of good cotton from unwanted dust and foreign matter.

RESEARCH FOR THE MOTORIST

Work on the problem of cylinder and piston wear, which involved 360 distinct engine tests and 15,000 measurements, has afforded good evidence that cold cylinder walls, with consequent corrosion, play the most important part in the wear of cylinders. Besides this work, the Research Committee of the Institution of Automobile Engineers is carrying out important investigations on the wear of valves and valve-seats, bearing problems, lubricating oil pumps, and

¹ Cmd 4483 H.M. Stationery Office (2s. 6d. post 3d.)

oil consumption. During the year the responsibility for road research has been transferred to the Department from the Ministry of Transport. Researches on road tars are being carried out at the Chemical Research Laboratory. Work on motor-car headlights at the National Physical Laboratory has led to a method for determining the light distribution which should be aimed at for a headlight beam.

PUBLIC HEALTH

Many of the researches of the Department have a direct bearing on public health. Chief among these is the work of the Water Pollution Research Board on water supplies and the prevention of pollution. Means for preventing the pollution of rivers by the discharge of effluents from beet sugar factories have been worked out, and the treatment of milk factory effluents is now being studied. One result of the Board's work is that future installations of coke ovens in the Tees area will be designed in such a manner that little or no polluting effluent will be discharged. A complete survey is being made of existing knowledge regarding the solvent action of water on lead. The effect of electric currents in leaden water-pipes on the lead content of the water is also being investigated. Work is also being done on water-softening processes.

At the request of the Home Office, the Department has arranged for an investigation to produce more efficient respirators for use in industrial processes as a protection against the inhalation of dust. This work has led to the production of a new respirator with which very satisfactory results have been obtained in tests in mines, quarries, and silica and asbestos works. Research is also being carried out on the detection of small quantities of toxic gases in the atmosphere, and on respirators to prevent the breathing of such gases. This work should result in affording better protection to workers in chemical and other factories.

The improvement of materials used in dentistry is also a subject of research under the Department, while x-ray examinations have been carried out in co-operation with the Medical Research Council on the structure of teeth. These have shown the existence of various typical forms of enamel, and an attempt is being made to correlate the occurrence of the different forms with tendency to decay.

INTERNATIONAL FIRST-AID CONGRESS

The fourth international congress for life-saving and first aid in cases of accidents will be held in the Rigsdag, at Christiansborg Castle, Copenhagen, from June 11th to 16th, under the patronage of the King of Denmark. An international exhibition, demonstrations, competitions, etc., are being planned for the same week. As the congress promises to be one of a far-reaching character, a tentative British committee has been formed, composed of the following, some of whom have already promised to read papers. An invitation is extended to all who are interested in the items of the programme: organization of international aid in case of large catastrophes; international organization of first aid in case of quick traffic; theoretical and practical training of physicians for purposes of first aid; organization of first-aid competitions; organization of salvage work in case of railway catastrophes; means to avert accidents by bathing, and organization of first aid; whether mines ought always to have medical practitioners at disposal; and occupational maladies.

The British committee of the congress comprises: Sir Thomas Oliver, M.D. (chairman); Professor S. L. Cummins, M.D. (Welsh National School of Medicine); Dr. Edgar L. Collis, M.D. (late Talbot professor of preventive medicine, University of Wales); Professor John Glaister, M.D. (Glasgow University); Colonel P. S. Lelean, F.R.C.S. (professor of public health, Edinburgh University); Colonel Donald J. Mackintosh, M.B., and Mr. Wellwood R. Ferguson (chairman of council and general secretary respectively of St. Andrew's Ambulance Association); Dr. D. A. Coles; Dr. Theodore Thompson; Mr. Frederick P. Mills (chief officer, Durham and Northumberland Collieries Fire Brigade Association); Mr. Ridley Warham (managing director, Ashington Coal Company, Ltd.); Dr. Gilbert Burnett (chief surgeon, National Fire Brigade Association); Mr. W. G. Webster, and Mr. Guy Mansell.

Further particulars may be obtained from Mr. G. L. Perry, secretary, Industrial Welfare Society, 51, Palace Street, S.W.1.

Reports of Societies

PRE-OPERATIVE INVESTIGATIONS

At a meeting of the Medical Society of London on January 22nd, with Sir JOHN THOMSON-WALKER in the chair, a discussion took place on "The Value of Pre-operative Investigations."

Dr. F. J. POYNTER, in introducing the subject from the physician's aspect, began by remarking that when he had a case in hospital which he believed to need operation he invariably asked the surgeon to meet him and discuss the case before the crisis. He always prevented, if possible, a hasty operation when there was time to spare for a review of the case. Empyema in childhood had not infrequently been looked upon as requiring an urgent operation, when, in fact, it was unusual if there was no time to review the case; sometimes as a result of such review mistakes were corrected. With regard to anaesthesia, he felt that forcible anaesthesia for children should be abolished as far as possible. He could not speak as an anaesthetist, but as a clinician he could say that he had seen highly strung children grievously affected by forcible anaesthesia. With regard to pre-operative investigations in general, it could not be doubted that they were proving of increasing value in assisting good surgery, though he was sure there would be general agreement that the long-established precautions to which the clinical physician was accustomed must not be relaxed. In spite of special tests they must strive to be good clinicians if they were to take the responsibility of advising operations. Speaking of blood tests, he said that the value of the blood urea examination was considerable in renal surgery, and he believed that in many ways the skilled examination of the blood had given much additional help to the physician and surgeon. The value of radiography as a pre-operative investigation would increase every year. His own difficulty was in the ability to interpret the shadows. In the condition termed "chronic intussusception" he had been helped by x rays. Of the value of x rays in detecting appendicular disease he desired to hear opinions. He deprecated the wholesale use of radiography as expensive, and as another tax on the patient, and he held that the physician should use it with a definite purpose in his mind. With regard to other investigations, the fractional test meal and the estimation of the free hydrochloric acid and the total acid were of established value. The condition of the patient in cases of hepatic disease and gall-bladder affections had always interested him, particularly from the point of view of possible haemorrhage after operation; the blood platelets in cases of jaundice were often normal, but when there was a tendency to haemorrhage these might be diminished. He desired opinions upon the value of intravenous injection of glucose when, in septic cases, jaundice began to be manifest, and an operation to liberate pus was required. Did this injection assist in preventing the development of hepatic necrosis? The pre-operative investigations were not without their disadvantages to the patient. A barium enema might cause much suffering, and a bismuth meal was not a pleasure. That was his reason for saying that a good clinician enhanced the value of pre-operative investigation, because he was aware of the strain which such investigations imposed upon the patient, and was able to decide which, if any, were really needed apart from curiosity.

Mr. NORMAN C. LAKE, speaking from the surgical point of view, said that one feature of pre-operative investigation was the economic aspect. While in some of the might be both feasible and advisable to have. Later set of investigations carried out, such as to develop a great consuming, both for doctor and for patient, to be expensive, so that there were practical application their unrestricted application. It might be a great life. inquire whether the modern intensive procedure, he proved had really improved the standard of surgery; and There were many who maintained that it

methods were capable of giving results comparing favourably with those obtained with the newer aids, but for his own part he was convinced that these new methods had brought about a great improvement. There were fewer gross mistakes in diagnosis and fewer unjustifiable operations, and while other factors were concerned in this improvement, pre-operative investigation had been the most outstanding. He divided such investigations into three categories: those devoted to the attainment of greater precision in diagnosis; those directed to the estimation of the patient's ability to stand the operation, and those which attempted to estimate the prognosis—this last restricted group, which had come into some prominence since the possibilities of sympathetic surgery, began to attract attention. It was of some philosophic interest to note that practically all new aids to diagnosis were by way of rendering changes more obvious to that finest of all senses, the vision. More confidence was evidently placed in that sense than in any other, and the public also insisted that "seeing is believing." It was true that the sense of hearing had been used in the case of the stethoscope, but even there the inventor could not resist the temptation "scope." He thought the method of investigation by smell had been insufficiently used in the practice of medicine. In a brief review it was impossible to touch on more than the most frequently used tests. There was no branch of surgery in which pre-operative investigation had been more intensively applied than in renal surgery. The ability to estimate the functional capacity of the kidneys had greatly reduced the mortality of prostatectomy and other operations. The more recent introduction of lipiodol injection of the vas, which clearly demonstrated the anatomy of the genital tract, was of limited application, but the corresponding tests for patency of the tubes in the female had proved of real diagnostic value. The technique of the barium meal and enema was now firmly established, though he felt there was room for improvement in the interpretation of results. In the case of gastric ulceration the method was fairly accurate, but even here a good deal depended upon the phase of the ulceration. The apparent radiographic size of the crater was dependent upon such factors as the surrounding inflammatory oedema and muscular spasm, which were only marked in the active phase, though, of course, it was in the active phase that the radiographs were generally taken. In the case of duodenal ulcer the results were far less satisfactory. Here again the phase of the disease must be taken into account. Deformities of the duodenal cap might be produced by other intra- and sometimes extra-abdominal causes. Passing to the appendix, he felt that the x-ray method of investigation was of little value. Large numbers of appendices showed slight variations from the normal which, with the backing of x-ray diagnosis, might be interpreted as pathological. The barium enema had proved its worth, but it was not infallible, and in the early stages of colonic carcinoma it might be very misleading. On the other hand, in diverticulitis its value was paramount. The fractional test meal he had found to be of small diagnostic value in the case of ulcer, except as supporting other evidence. The test for occult blood was a very accurate one, but it was obviously an indication of the presence of disease rather than of its nature, and might be tantalizing and misleading. On the subject of cholecystography he was rather a heretic. It must not be overlooked that four separate factors were involved—namely, the ability of the intestine to absorb the dye, of the liver to secrete it, of the dye to reach the gall-bladder, and of the walls of that structure to concentrate it. But the test was frequently of value, and when a filling defect due to a calculus was present it was absolutely diagnostic. It is fairly safe to say that the value of all pre-operative tests was enhanced by their repetition.

EDMUND I. SPRIGGS did not agree with the statement that radiology was not of value in appendicitis. It was, sometimes it was not; with an appropriate technique over 80 per cent. of appendices could be demonstrated; and with experience abnormal appen-

dices can be recognized. As to the costs of tests, which had been mentioned by Mr. Lake, that consideration came in, of course, but he did not think it was a point with which, as scientific physicians, they ought now to concern themselves; if it was desirable to have investigations made the cost would ultimately be provided. He dissented also from Mr. Lake's general conclusions with regard to cholecystography, a method which he regarded as most valuable. Formerly there was much confusion as between the duodenum, the appendix, and the gall-bladder, but now, thanks to radiology, it can often be demonstrated if these organs are normal or not. Negative as well as positive findings had value. Some years ago he went through 500 consecutive cases, comparing the provisional diagnosis made by his colleagues and himself after examining the case clinically, with the eventual diagnosis at which they arrived a week or ten days later, after making such investigations as were appropriate to the case. It was only right to say that these 500 were not ordinary cases; a great many of them were cases of difficulty. In 40 per cent. the opinion of his colleagues or himself as to the diagnosis was the same after the investigation as it had been before; in 19 per cent. it was quite different, the investigation having revealed something unknown previously. In the remaining 40 per cent., while the diagnosis was modified as a result of the later investigation, it remained essentially the same. For want of investigations a great number of people had been treated for complaints which they had not got, and hundreds, probably thousands, of unnecessary operations had been done, while similarly for want of such investigations great numbers of necessary operations had not been done.

Mr. W. H. OGILVIE took a contrary view to Dr. Spriggs with regard to the value of cholecystography. When that method first appeared he used it considerably, but as time had gone on he had used it less and less. He had had a good many gall-bladder cases returned by eminent radiologists as normal which had been found at operation to have very obvious disease. Every surgeon was familiar with the type of gall-bladder which was otherwise normal, but had a number of small stones, and the healthier the gall-bladder and the smaller the stones, probably the more irritable the symptoms. "Strawberry" gall-bladder could not be demonstrated by cholecystographic methods. It was true that a diseased gall-bladder should concentrate the dye, but the differences in shadow were so considerable that he did not think the degree of concentration could be used with any certainty in diagnosis. The method also had definite dangers.

Dr. T. JENNER HOSKIN referred to the importance of preliminary investigation in Graves' disease. He did not think the basal metabolic rate was quite as accurate as might be hoped for, and very often the resting pulse in these cases was nearly as accurate. X-ray examination was important to see that there was no substernal goitre; examination of the larynx should also be made to ensure that both cords were satisfactory before the surgeon acted. With regard to prostatectomy, he pointed out the importance of the examination of cardiovascular function. He had been specially troubled with low blood pressure in these cases; high blood pressure had never worried him at all.

Mr. EARDLEY HOLLAND approached the subject as a gynaecologist, saying that gynaecologists were apt to concentrate their attention on the pelvis, and thereby sometimes overlooked other factors and were led into error. The whole discussion simply drove home the lesson that the complete history must first of all be taken—a thing which specialists were apt to neglect—and that a complete medical examination must be made. Mr. THORP EDWARDS referred to tests in the lung, and pointed out that some of these introduced risks, and that unless these risks were appreciated the minor operation to which the patient was subjected might turn out to be a major disaster. He referred particularly to the introduction of lipiodol into the lung. On several occasions he had seen a gross cellulitis of the neck follow. Sir WILLIAM

WILLCOX agreed that while appendicitis should not be diagnosed on x-ray examination, given a case with clinical symptoms which pointed to chronic appendicular trouble, and having excluded by investigation other causes, the x-ray examination did give most valuable assistance. He added that formerly one was afraid of operation in diabetic cases, but now this fear obtained no longer; it was important to see that there was no acidosis, but he did not mind if there was a little sugar in the urine. He thought it a mistake to overdo starvation before operation, and to let the patient undergo the serious strain of surgical intervention when he was suffering from lack of nutrition. Mr. GREEN-ARMYtage referred also to the importance of a wider investigation in gynaecological cases, particularly as to the discovery of the cause of the frequent cases of backache. Sir JAMES DUNDAS-GRANT narrated a personal experience of appendix trouble, in which it had been possible to palpate the appendix while lying in a hot bath. Mr. ERIC LLOYD referred to some orthopaedic problems bearing on the subject. Mr. WILLIAM IBBOTSON spoke on the role of the physician and bacteriologist in tonsil cases, saying that unless they were in co-operation he was sure that tonsillectomies would continue to be done without real justification. He also instanced a case of the rare condition of syphilitic stricture of the oesophagus in which radiography completely cleared up the diagnosis; from the symptoms it was thought that the patient had carcinoma. Mr. ALBAN ANDREWS mentioned early renal tuberculosis as a good example of a condition in which clinical and special investigation had an almost equal importance. Dr. MAURICE SHAW suggested how the physician might proceed when his surgical colleague asked whether a patient was fit for the operation. His survey would include, in the first place, the lungs, then the cardiovascular system, and then the kidneys and liver.

In replying to the discussion, Mr. NORMAN LAKE said that after some twenty-five years' experience of surgery the conditions which necessitated urgent operation became, to his thinking, fewer and fewer. It seemed to him that perforated ulcer, a perforated viscus in the abdomen, and some violent haemorrhage almost exhausted the list of emergencies. Sir J. DUNDAS-GRANT suggested strangulated hernia, but Mr. LAKE said that even this was not as urgent as those he had just mentioned. His conclusion on the whole matter was to paraphrase Abraham Lincoln: "You may diagnose some patients all the time, and all patients sometimes, but you cannot diagnose all patients every time."

FACTORS INFLUENCING RENAL FUNCTION

At a meeting of the Section of Urology of the Royal Society of Medicine on January 25th, with Mr. CLIFFORD MORSON in the chair, the subject for discussion was the factors influencing renal function, together with an assessment of the various methods of investigation.

Dr. T. IZOD BENNETT said that the factors which might adversely influence renal function were numerous and complicated. He divided them into intrinsic factors, such as anatomical changes, and extrinsic factors—namely, mechanical, circulatory, lymphatic, and nervous changes. Anatomical changes, of course, could be multiplied to include every type of neoplasm and many diseases over and above the large group which he had included under the term "Bright's disease." Physicians and pathologists together agreed that one of the large groups which constituted Bright's disease, and was sometimes still described as chronic interstitial nephritis, demanded renaming, and the term "ischaemic nephritis" was offered. Long before such cases manifested themselves as nephritis they were indicated to the clinician owing to the severe degree of hypertension which was present. It was only a small proportion of the total number of such cases—perhaps 10 per cent.—which terminated by renal failure and uraemia; the far commoner termination was some cerebral catastrophe or left-sided cardiac failure. True inflammatory nephritis was often in its late stages indistinguishable from ischaemic nephritis, being character-

ized by sclerosis of the kidneys and extreme hypertension. Careful examination of the blood pressure should form part of the routine examination in every urological case. Urological surgeons were people who appreciated accuracy, and the modern sphygmomanometer was an instrument of great precision. If urologists studied the blood pressure they would avoid occasional catastrophes and add to the knowledge of the subject. Apart from cases of permanent diminution in total blood supply to the kidney, cases occurred in which ischaemia was temporary, but might be sufficient to produce severe alteration of renal function. Everyone had had experience of cases in which disease had apparently followed the passage of an instrument into the lower urinary tract. Personally he believed one was here faced with a reflex ischaemia resulting in suppression—a nervous mechanism. Blood changes affecting renal function must be considered under two headings, the first being changes in the quality of the blood reaching the kidneys. These changes might be due to bacteria and their toxins, to chemical poisons of known character, such as mercury and lead, and to chemical poisons supposed to be of endogenous origin. But what he particularly wished to speak about were the changes in the relative normal constitution of the blood. It was known that renal failure would bring about changes in the blood chemistry. Such changes appertained far more to the relative distribution or relation of the various chemical substances in the blood than to the appearance of new substances. Although alterations in renal function might bring about considerable changes in the relative concentration of the various normal chemical constituents, it was not nearly enough realized that if the relative concentration of such substances were altered, this alone might produce a diminution in the secreting capacity of the kidney. Changes in the constitution of the blood might be causes as well as effects of alteration in renal function. Nitrogen retention of extra-renal origin was a subject which had received considerable attention of recent years. If for any reason the water supply through the kidney were impaired it would create nitrogen retention, and this might cause a still greater interference with renal function, and push the patient into actual uraemia. An important aspect of this question was connected with another group of surgical catastrophes, in which, after a severe operation, suppression of urine, sometimes followed by death, occurred. French workers had shown that if observations were made on the blood urea of a patient for several days prior to operation and for a certain time afterwards, the blood urea would be found to rise for a time after severe operation. It was claimed by some surgeons that a prophylactic injection of normal saline prior to operation was of the greatest value in preventing catastrophes. Dr. BENNETT then proceeded to discuss the methods of investigating renal function. Cystoscopy, pyelography, and x-ray examination of the urinary tract were of the highest value. The urea clearance test of van Slyke was probably far more valuable than any single biochemical test which it had been customary to use hitherto; but it would be regrettable and dangerous if it were forgotten that a test like that represented only the patient's renal function at one particular moment, and must be repeated at varying periods for some time before any fair picture of what might be regarded as the patient's capacity was obtained. The test made a great appeal because, after taking a sample of blood and one or two samples of urine, the biochemist was able to supply the clinician with a fairly accurate figure, giving the patient's function as a percentage of normal. It would also be regrettable if the simplicity of the final figure given by this test should persuade clinicians to give up examining closely the figures furnished by a fuller analysis. He wished to make a serious suggestion to his surgical colleagues. With all their care and with the increasing technical perfection, tragedies were still encountered from time to time, and it would be of value, he thought, if whenever a renal case was lost owing clearly to renal failure of some type, the plan were adopted of holding a post-mortem inquiry of a different character from that usually followed. It was generally of very little interest to know the degree of renal damage shown post mortem, and it would be of far greater interest if careful blood examination prior to death were

made so as to enable it to be said afterwards that the patient died of extreme nitrogen retention, or of acidosis, and so forth. A complete blood analysis often enabled one to state with precision the mechanism of death, and so forewarned one for future occasions. He added that the estimation of the daily output of urine was of great value, particularly when coupled with an estimation of fluid intake.

Mr. DUNCAN MORISON said that, from a urological aspect, the lesions which adversely affected renal function did so by producing some hindrance to the normal outflow of the urine. The hindrance induced a stasis, and soon there was established a state of back pressure which was transmitted to the kidney, impairing its activity and leading to nephrosis. In addition to stasis there was infection, and the two were closely related. He reviewed briefly certain forms of insidious obstruction. Two main types occurred in the urinary tract—primary and secondary. With regard to the primary type, throughout the conducting system from the renal pelvis to the external meatus there were certain sites at which obstruction most commonly occurred. Those nearer the kidney would, as a rule, produce more rapid functional impairment than those more remotely situated, though exceptions to this rule might occur. The speaker discussed different types of obstruction as related to different sites. He pointed out that all these lesions, by impeding the normal outflow of urine, produced proximal strain and the occurrence of stasis; and stasis aided in renal failure by encouraging and harbouring infection. Secondary obstructive lesions followed upon infection, either of a primary character, in the genito-urinary tract, or secondary, due to some outside focus or general systemic cause. This was a large group, and one of interest to the urologist. He did not need to enlarge on the manner in which repeated infection led ultimately to the formation of fibrous tissue. A typical example of the primary infection was the gonococcal. There was also a lesion frequently found in women which was of special interest. It was commonly attributed to the trauma of childbirth and repeated attacks of cystitis. The same bladder picture was found as in chronic fibrous prostate in the male, and the symptomatology at times was remarkably similar in both sexes. In a few observations of methods of investigation, he said that in order to obtain a proper estimation of the lower urinary tract, particularly the bladder neck, it was advisable to employ the lateral as well as the end view with the urethroscope. From investigations carried out under local anaesthesia much information regarding the bladder base and neck could be obtained. For the determination of ureteritis it was essential to employ bulb bougies or catheters—but he preferred bulb bougies—whereby the calibre, site, and extent of the ureteritis could be estimated.

Dr. CUTHBERT DUKES limited himself to discussing, by means of diagrams, three factors which influenced renal function tests—namely, the effect of operations, of intestinal obstruction, and of urinary obstruction. The information he showed in a series of graphs was derived from performing the same tests on the same patient day after day, in some cases for two or three weeks. As a test of renal function he had carried out the urea clearance test, which really measured the amount of blood which would be cleared completely of urea per minute if the kidneys worked in that way. He described the clearance test, and pointed out that a defect in renal function might be revealed by this test when the blood urea was still within normal limits. The influence of a minor surgical operation (excision of haemorrhoids) on renal function showed that on the day following operation the urea clearance value fell from 76 per cent. to 52 per cent., but it returned to the original level the next day. In the case of a major surgical operation (excision of rectum for cancer) the urea clearance test prior to the operation showed 103 per cent., and then a temporary decline in urea clearance was followed next day by a period of hypertension. He added that van Slyke spoke of anything from 75 to 120 per cent. as within normal limits; but there was really nothing to worry about until the figure shown by the clearance test was 40 per cent. or

less. He had compared a hundred cases at St. Peter's Hospital to discover the value of the various tests. From an estimation of the figures it was probable that in the surgical type of case the estimation of the blood urea alone gave all the essential information which the surgeon really wished to have. Different forms of renal function tests might be required for the investigation of different types of disease. Whether the urea clearance test had any future in surgical practice or not must be decided by future experience, but it was of great interest scientifically, and, he thought, of value in medical cases.

Dr. KENNETH WATKINS said that he had had the privilege of studying for twelve months under Dr. Hugh H. Young at the Brady Urological Institute of the Johns Hopkins Hospital, Baltimore. There he had been impressed by the value of the phenolsulphonephthalein test, and had used it since his return. The test was first introduced in 1910, but it was not until a great deal later, when fractional methods were employed, that it came into its own. At the Brady Clinic specimens were taken each half-hour after the injection of phenolsulphonephthalein, and he showed a graph of the excretion of the normal individual. After the injection of 6 mg. of the dye the appearance time was within three minutes. He thought the test gave an excellent graphic representation of the recovery function following relief of obstruction. Dr. Young had insisted that it was not a return to a certain definite level of renal function which was important, but that the return should represent the greatest ability of each individual case. In that way Dr. Young had operated on many cases successfully in which the actual dye elimination was poor. So far as differential renal function tests went, he thought this test also was of great value, and probably gave much better evidence than the other tests at one's disposal. The test was simply carried out. A large volume of water should be given before it was started. He had come back from America with a very favourable impression of this test, which was used widely in American urological practice.

Mr. E. W. RICHES felt that, as regards renal function tests in general, the clinical condition of the patient was the most reliable index of renal function only in extremes of good or bad function, and it was in borderline cases that the laboratory tests were of most value. From the surgical point of view particularly, tests of this nature were valuable in a prostatic case. He thought that all prostatic cases required some renal function test. He had taken a figure of 60 per cent. with the van Slyke clearance test as the borderline to indicate whether a one-stage or a two-stage operation should be performed, and since doing so he had not lost a case after prostatectomy. After removal of a tuberculous kidney the renal function tended to rise, provided there was no secondary infection in the bladder or the opposite kidney. The presence of infection seemed to him the most potent single factor in causing a depression of the renal function. He felt that, from a surgical point of view, the urea clearance test was the most valuable of the tests available, especially in prostatic cases. If it was performed, it did not depend on any artificially produced diuresis. It was taken with the patient just as he was.

Mr. H. P. WINSTONY-WHITE said that there had always been too great a tendency to consider that good renal function indicated a proportionately good prospect of recovery from operation. In operations on the urinary tract tests of renal function were useful, but they were misleading unless equal consideration was given to the clinical facts. Discussing the effect which bladder drainage had on renal function, he said that he constantly made use of two types of bladder drainage—namely, the indwelling catheter and suprapubic cystostomy. In cases of prostatic obstruction where prostatectomy had to be considered, the effect of the obstruction might be so severe that even suprapubic cystostomy was contraindicated. The coaxing back of an extremely debilitated patient to a state of health by stages was reflected in the renal function tests. He described his practice with the water test. Normally, if 50 oz. of water were drunk in the space of half an hour, it was excreted roughly up to about 75 per cent. in four hours. Very considerable delay

in excretion was noted in advanced cases of prostatic obstruction. He had been in the habit of testing by simply marking the specific gravity. One charted the urine excreted every two hours and the specific gravity was noted. With regard to the concentration test, he did not find it anything like so reliable as the water test.

Dr. GEORGE GRAHAM considered the effects of alkalosis and acidosis, pointing out that the condition of alkalosis could be produced by vomiting after operation. When people vomited after an anaesthetic they were given an alkali, whereas in many cases they should be given either acid or sodium chloride intravenously, or glucose together with insulin, and a good many of the people who were likely to develop uraemia after vomiting could be saved in that way. On the other hand, some patients had not alkalosis but acidosis. These people could be helped by giving them alkali. A person who had got a severe acidosis very often would show a condition similar to that of the air hunger which occurred in diabetic coma; whereas a patient with alkalosis always had very quiet breathing. For the purpose of making certain, however, as between the two conditions, it was necessary in the very bad cases to determine the alkali reserve. He was a little sceptical of the treatment of acute nephritis by starvation. He had had equally good graphs of recovery in patients who had had a reasonable amount of protein given to them. He believed that Dr. Bennett had been unnecessarily gloomy as to the prognosis in cases of acute nephritis.

Mr. SWIFT JOLY said that in the examination of cases requiring prostatectomy he placed a good deal of reliance on the elimination of water, and he always tried to push up the excretion of water before the operation, endeavouring to double the normal amount. It was interesting to chart the quantity of urine in twenty-four hours with the quantity of fluid intake. Very often one did get a considerable lag in the quantity of urine, and sometimes no response to the fluid at all. The cases in which there had been voluntary reduction of the intake of fluids were extraordinarily fatal if one operated on them without due preparation.

ENVIRONMENT AND ACUTE RHEUMATISM

'At a meeting of the Sections of Epidemiology and Children's Diseases of the Royal Society of Medicine on January 26th, the subject of discussion was "Acute Rheumatism and Chorea: Social and Environmental Factors." The chair was taken by Dr. J. D. ROLLESTON.

Dr. J. ALISON GLOVER began by referring to the 1927 report of the Child Life Committee of the Medical Research Council on the subject of "Social Conditions and Acute Rheumatism." This embraced the medical and social histories of 721 rheumatic families, 200 control families, and 2,000 children living in Poor Law schools. The medical particulars included familial inheritance and incidence, the incidence of sore throat and throat conditions generally, and in particular tonsillectomy; and the social points inquired into embraced maternity care, exposure, sleeping accommodation, clothing, cleanliness, distance of residence from school, and occupation and income of parents. In spite of a careful study of the results of the inquiry, the findings were declared to be largely negative; but the speaker considered that poverty, overcrowding, malnutrition, and dampness were associated factors of great significance. Gray Hill and Allan seemed satisfied that it was not possible to define the "rheumatic type" of child on any bodily or pigmentary standard. The Child Life Committee had stated that if children of the hospital class were divided into three categories according to their degree of poverty then the very destitute poor showed a lower rheumatic incidence than did those of the other two classes. Still Dr. Glover expressed his belief that, in the main, the incidence of acute rheumatism was in direct proportion to the degree of poverty. The chief advance on the subject was marked by the identification with the cases of the *Streptococcus pyogenes*; while the work of Coburn in the United States

established a direct correlation between the geographical and the seasonal distribution of haemolytic streptococcal throat infection and acute rheumatism. Paul and Salinger made a study of fifteen rheumatic families, and found that non-specific respiratory infections occurred before the appearance of characteristic acute rheumatism. Also, the parents in rheumatic families did not enjoy such good health as in other families.

Dr. REGINALD MILLER said that one had to consider three sets of causative factors in relation to this subject: (1) the bacterial cause circulating in the blood; (2) the predisposing factors; and (3) the exciting factors. The disease, it was agreed, was essentially one affecting the children of the poorer classes, though it was doubtful whether it could be called a true poverty disease in the sense that squalor and poverty determined its class incidence. If it should be proved that the causative agent of juvenile rheumatism was a haemolytic streptococcus, ideas would need to be considerably rearranged. He thought the report of the Special Committee of the British Medical Association¹ was correct where it stated that juvenile rheumatism was essentially a disease of children of the artisan class who lived in damp houses in industrial towns, attending public elementary schools under compulsion, and suffering from infected tonsils. At present, however, no single factor could be held culpable.

Dr. W. S. C. COPENAN, though a believer in the infective origin of acute rheumatism, considered that secondary factors could well modify the clinical course of the disease. The following factors could not be left out of consideration: soil, climate, barometric variations, wind, degree of damp, temperature, poverty, ventilation, and overcrowding. He thought that the subjects of this disease had a defect in their heat-regulating mechanism of the skin. He agreed in attaching importance to the dietetic factor; it was not merely a question of the total caloric value of the food taken, but, as Dr. Warner suggested, it might extend back to the beginnings of the disease. As overcrowding was invariable in the case of people below a certain poverty level, it would be difficult to assign to it a special place in the causation of rheumatism. He advocated a careful study of what were regarded as minor factors; he was not of those who considered that clinical research had been exhausted on the subject.

Dr. E. C. WARNER considered that an infective origin was not demonstrable for all rheumatic diseases; for instance, in the case of chorea without carditis there was a good deal of evidence against the hypothesis of an infective encephalitis. Also, in these cases the sedimentation rate did not show any rise from the normal, but as soon as carditis occurred—even before it became manifest clinically—the sedimentation rate rose. A study of class incidence and familial incidence seemed to suggest that an important part in causation was played by a metabolic factor. In the case of many rheumatic families which were inquired about there was no deficiency in the total caloric value of the food taken, as it averaged 3,250 per man-value per day; also the protein intake was sufficient. An invariable observation was that rheumatic children manifested a dislike for fatty foods—in the form of fresh milk and butter—in comparison with the likes of non-rheumatic children; but the rheumatic subjects showed a great fondness for potatoes. At Christ's Hospital the diet was generous and was rich in animal fats, and five-year comparisons showed a steady decrease of rheumatic diseases there. In an inquiry Dr. Warner found that in cases of chorea the calcium content rose in the cerebrospinal fluid, and at the same time the phosphorus content fell. Many observers had remarked on the occurrence of a period of general debility in those who later developed rheumatism of chorea, and the speaker thought this debility might be due to defective diet.

Dr. R. J. LLEWELLYN said that multiple stimuli, such as heat rays, light rays, varying barometric pressure, were constantly impinging on the human organism, and the latter either swiftly adapted itself to them or fell a victim to disease. Man and his environment were one and

¹ British Medical Journal, Special Supplement, July 3rd, 1925.

indivisible. Rheumatism, he thought, was mainly a matter concerning the skin, being only secondarily one of bones and joints. In the adaptive processes of the body the cutaneous glands, especially the sebaceous glands, played a marked part. In infancy and young childhood those glands were comparatively inactive, and so the supply of protective and lubricating sebum was defective, and hence the skin was very sensitive to humidity because of the defective heat retention. Whether any particular child would fall a victim to rickets or rheumatism depended largely, he thought, on its inherited make-up.

Dr. C. BRUCE PERRY (Bristol) remarked that his own findings on the sedimentation rate of the blood in uncomplicated chorea were similar to those which Dr. Warner had just stated. Also that the sedimentation rate would rise as a precedent to clinically recognizable carditis. He spoke of the investigation into the incidence of cases of rheumatism in Bristol and the three surrounding counties which had been made, and said that a closer inquiry into the figures for Bristol itself showed that there were greater differences for various parts of Bristol than between Bristol as a whole and the three counties. In the city ward with the highest rheumatic incidence the figure was 3.7 cases of rheumatism per 1,000 of the population, whereas the lowest incidence (Clifton and Redland) was 0.15 per 1,000. If, as Dr. Glover contended, a concentration of haemolytic streptococci played a very important part in this striking distribution, the incidence of scarlet fever over the same period should show a parallel distribution; but that was not the case, nor was it so in the case of diphtheria. The Bristol inquiry, he thought, seemed to show that it was not the infection itself which enabled the disease to gain a footing, but rather the soil, the child's diathesis, and the environmental conditions.

Professor J. A. NIXON (Bristol) said comment had often been made on the fact that the incidence of rheumatism in Poor Law schools was low—lower than among children of the same social class who attended the ordinary day schools. The disease was also largely passing from the great public schools. Another form of closed community in which the disease was very rare was the institution for mental defectives. Yet in these institutions there had been a number of outbreaks of scarlet fever. A useful line of investigation, he suggested, was to study the communities in which rheumatism was practically absent.

Dr. LEONARD FINDLAY said it was now the general belief in the profession that acute rheumatism was an infectious disease, and, if that were so, it would be natural for social conditions to influence its onset, either by favouring transmission or in the way of deterioration of general health and lowered resistance. He did not think the actual cause of the disease had yet been established, despite the arguments in support of arguing the haemolytic streptococcus. There was, he felt sure, some factor other than a microbial one, was it a symbiosis, or was it merely a matter of environmental influence? Certainly the great need among the rheumatism-inflicted community was for decent houses to live in.

Dr. E. W. GOODALL asked whether, in the cases specially mentioned by Dr. Glover, tonsillitis was an associated condition.

Dr. GRAY HILL (Carshalton) said that among the 3,000 inhabitants of his institution there was little rheumatic manifestation except chorea. The soil was a chalky one, and the children lived in excellent hygienic conditions, with a generous dietary. He considered that rheumatism was largely due to bad environmental conditions.

Dr. GLOVER, replying to Dr. Goodall, said that in practically all the cases of rheumatism he referred to there was also tonsillitis. A high tonsillectomy rate did not increase resistance to rheumatic invasion; indeed, the opposite seemed to hold. It would be well worth making an inquiry into a number of rheumatic families, and an equal number of control families, keeping an exact record of the illnesses of every member, week by week, on parallel lines, and especially to keep going a weekly swab examination.

Dr. REGINALD MILLER, in reply, agreed with Dr. Nixon as to the importance of studying rheumatism-free communities; this had been done by the B.M.A. Committee in the case of certain schools. He agreed that people in institutions for the mentally defective were notoriously free from rheumatism and heart disease, and that provided one of his reasons for contending that the wear and tear and exposure incidental to compulsory school attendance by children of the poor was a factor in the incidence of rheumatism. At the present stage of knowledge it was, he thought, a serious matter for anyone to question the infective origin of acute rheumatism.

THE GENERAL PRACTITIONER AND MIDWIFERY

At a meeting of the Edinburgh Obstetrical Society, on January 10th, Dr. WILLIAM HAMILTON read a paper on "The Position of General Practitioner Midwifery."

Dr. Hamilton began by giving a general account of the conditions under which the midwifery of general practice was conducted. He discussed the economic basis, the nature of the assistance available, the services actually rendered, and the technique adopted. Chloroform, he said, was given at the end of labour in every case. Primigravidae received heroin and hyoscine fairly frequently, while multiparae rarely received these drugs. Pituitrin was used freely; it had been given to 34 per cent. of primigravidae and to 42 per cent. of multiparae. No bad effects had ever been observed. Its use had permitted a more free administration of anaesthetics without compelling recourse to delivery by forceps, had diminished the forceps rate among multiparae, and had had a beneficial effect in securing a rapid and physiological third stage. In only three of 1,409 cases had manual removal of the placenta been required. Lyol was the only antiseptic used. The technique was a compromise between what was theoretically desirable and what was economically, domestically, and professionally practicable. The results indicated that there was no positive correlation between elaborate technique and the prevention of maternal morbidity and mortality. The speaker next presented a detailed analysis of 1,409 cases attended in a partnership practice since the war; he considered these were a true sample of obstetrical cases. Each patient received on an average 12.4 visits in her home between the beginning of the eighth month and the end of the puerperium. During the years 1925-33 in 1,164 pregnancies the abortions had equalled 7.6 per cent. of the live births and 7 per cent. of the total pregnancies. Of 1,434 foetuses delivered during 1919-33 almost exactly 17 per cent. were delivered operatively. The operative delivery rate was:

	Primigravidae	Multiparae
Occipito-anterior cases	31 per cent.	17 per cent.
Perforated occipito-posterior cases	41	43
Breech cases	43	46

Severe laceration during delivery was confined to primigravidae, and very largely to persistent occipito-posterior and breech cases. Among multiparae, whatever the presentation, the laceration rate was lower in the operative than in the spontaneous cases. Intra-natal and neonatal deaths actually or possibly due to dystocia were 15 follows:

	Primigravidae	Multiparae
Occipito-anterior cases	36 per cent.	66 per cent.
Perforated occipito-posterior cases	23	23
Breech cases	113	113

Over the whole series the infection rate was slightly higher in operative than in spontaneous cases, but the reverse was true of occipito-anterior cases both in primigravidae and in multiparae. Severe puerperal sepsis was confined almost entirely to women who had been delivered spontaneously. The five fatal cases of puerperal sepsis occurred in women who had been delivered spontaneously and without laceration and with a minimum of vaginal examination or with none. From these and other facts he was compelled to conclude that the occurrence and severity of puerperal sepsis depended very largely on

factors peculiar to the woman herself. The maternal death rate in this series of cases was 6.5 per 1,000. The actual admissions to hospital for medical and obstetrical reasons were: ante-natal 1.2 per cent., intra-natal 2.4 per cent., puerperal 1.3 per cent.

Dr. Hamilton finally discussed the question of maternity services in Scotland, and brought forward evidence to show that maternal mortality rates in different types of areas did not vary with the nature of the service, and that areas where maternity services were rendered very largely by general practitioners had on the whole a lower death rate. After explaining the impossibility of basing a maternity service either on maternity hospitals or on certificated midwives, he pointed out that general practitioner midwifery was almost invariably conducted in circumstances where equipment and nursing assistance alike were inadequate, and indicated directions in which improvements that were economically practicable could be made. He concluded that the results of general practitioner midwifery were good, and might be better still if the general practitioner were properly supported by the Department of Health and the public health authorities; and that no advance towards the solution of the problems of maternal mortality and morbidity was possible without proper utilization of the general practitioner.

SIMPLER PATHOLOGY

At a pathological meeting of the Liverpool Medical Institution, held on January 18th, with the president, Dr. H. R. HURTER, in the chair, Professor J. M. BEATTIE read a paper entitled "A Plea for a Simpler Pathology."

This communication was in the nature of a protest against the specialization which is becoming marked in the teaching of pathology. It was maintained that the fundamental facts of disease processes were being neglected, and that emphasis was being laid on theories, elaborate classifications, and obscure pathological details. Evidence of this was given from pathological literature. Professor Beattie suggested that the specialized research which was being so elaborated in pathological institutes and the craving for publication were largely responsible for this unfortunate state of affairs. The teachers of pathology, he maintained, were not now doing that "grinding" course which was so essential for real training in every branch of the work. They were urged to publish and to publish—but the work in this "grinding" stage did not lend itself to publication, and therefore it was not of any use to the man who, if he hoped to be a successful applicant for a teaching post, had to present a long list of publications. His real training and teaching ability were secondary considerations. Examples of the specialization and the mania for classification were elaborated by reference to the literature of the reticulo-endothelial system, of the classification of diseases of the kidney, and of tumours of the brain. No two authors agreed as to the definition of the reticulo-endothelial system, and the speaker held that the differentiation between cells should be based on an examination of the living cell and not on the stained, dead, and distorted cell. He saw no special value in the classification of diseases of the kidney, and none at all in the elaborate classification of gliomata. What the student or practitioner should know was what changes were produced in the various organs as the result of toxic agents, and chemical and other poisons. The clinician should be able to picture these conditions, but not necessarily give them a name. He should have studied the simple beginnings of disease and the changes which followed and which produced the more complicated pathological picture, rather than be able to describe the complicated picture without a knowledge of how it was built up. In the discussion which followed Dr. T. N. A. JEFFCOATE said that there was already a tendency for gynaecological pathology to become simplified—especially in so far as the diseases of the endometrium were concerned. Moreover, he considered that gynaecologists were fortunate in being responsible not only for the clinical side of their subject but also for the pathology.

CORRESPONDENCE

Legal Ownership of X-Ray Films

SIR,—Your most interesting article on the above question, in the *Journal* of January 13th last, has been read by many members of the British Institute of Radiology, and, as president of this body, it has been left to me to write to you.

The matter has frequently been discussed by the Medical Committee of this Institute. As there has never been an action at law to settle the point we have come to conclusions similar to those expressed in your article—namely, that intention of the parties, together with the usual custom of our profession, must govern the matter. The question has not infrequently been the subject of acrimonious correspondence, and from time to time consideration has been given to the advisability of a friendly action in the Law Courts in order to settle the matter by means of a decision. There seems to be no doubt that a legal decision would be given on the above lines—intention and custom—and, so far as can be made out, would certainly follow the many cases already forming precedents in the case of the photographer. There seems to be no doubt that the film is the property of the radiologist, and is the means whereby he makes a record for the advantage of his report and for the use of the medical man at whose instigation the consultation takes place. There is no absolute compulsion (short of definite arrangement) for a film to be taken, and there are many cases in which all that is required is an examination on the fluorescent screen. Here custom comes in, and it is usual for a film to be taken. Naturally the radiologist will file his films for such period as seems good to him, and will certainly do so in cases in which they may be required either to watch the progress of a case or in the event of medico-legal action. There is, however, no legal compulsion upon him to do so. Further, it is the custom of the radiologist in this country to be as considerate as he can be of the needs of the patient and of other medical men, but this naturally has its obvious limitations.

There would seem to be no room for doubt that x-ray films taken in hospital are the property of the hospital; indeed, this point has long ago been settled, though not in a court of law. The same argument would surely apply to a patient in a nursing home which has its own x-ray outfit. Here again the film is usually taken to assist the radiologist in making his report, and also to enable him to discuss the x-ray findings with the medical practitioner in charge of the case—and this follows the custom pertaining to any work in private.

In one class of case both intention and custom seem to have their best example. I refer to x-ray examination done for the insurance companies in cases that are going to litigation. Here the films become the property of the insurance company and/or their medical referee. It is conceivable that the radiologist himself, in the early days of radiography, may be to blame in that he appeared to exaggerate the importance of the print, and thereby conveyed to the public a wrong impression.—I am, etc.,

London, W 1, Jan. 23rd.

STANLEY MELVILLE.

The Sterilization Report

SIR,—In the Report of the Departmental Committee on Sterilization, para. 94, p. 50, the committee calls attention to the need for further research to determine whether pre-puberty vasectomy is likely to exercise any prejudicial effect on physical development by arresting the growth of the interstitial cells of the testis.

May I draw attention to the fact that Dr. Hammond, F.R.S., at the School of Agriculture, Cambridge, has

recently performed vasectomy on a number of young male rabbits, in which the later results show that the ligation of the ducts does not interfere with physical or sexual development, or capacity for sexual intercourse? We must, of course, be cautious in applying the results obtained from operations on animals to the human subject; but in view of the facts already known about the absence of prejudicial effects from vasectomy in the human adult, and the strong probability that the results obtained in rabbits are applicable to other mammals, including man, we may, I think, legitimately conclude, in the absence of evidence to the contrary, that vasectomy in the human subject performed before the age of puberty is not likely to interfere with physical or mental development or sexual capacity.

The matter is important, because some experts are inclined to suggest that, in view of possible prejudicial effects, an age limit should be fixed below which vasectomy should not be performed in the human subject, and the committee has suggested that the age should be the attainment of physical maturity (para. 91, p. 48). Any such limitation would, however, add to the administrative difficulties which already attend the adequate supervision and control of young and adolescent mental defectives, and, if not necessary on physiological grounds, the decision as to the age at which the operation should be performed should surely be left to the medical experts concerned, having regard to the circumstances in each individual case. I should add that Dr. Hammond's results were not available in time for consideration by the committee before issuing its report, but they are quite definite, and would, I think, fully justify the reconsideration of the question of fixing an age limit.—I am, etc.,

Leicester, Jan. 22nd.

C. J. BOND.

The New Cancer Problem

SIR,—The letter on the above subject, by Mr. Hastings Gilford, in your issue of January 20th has interested me greatly. I well remember the beautifully turned out and excellently illustrated reports of the early days of cancer research; the proud boast (well founded) that the few milligrams of original Jensen tumour had in a few years produced, by mouse inoculation, so many tons of cancer! But even then I anticipated the disillusionment that now seems to have overtaken cancer researchers. *Tout le monde est sage après coup*; but thirty years ago, on reading a paper on the origin of new growths before the Cork Medical and Surgical Society, I said: "When we know why a blade of grass grows and why a fertilized ovum becomes endowed with such tremendous energy, then we may understand how a malignant tumour grows." Does not all this disappointment arise from the simple fallacy of regarding cancers and sarcomata as essentially abnormal? In what essential respect does a cancer cell differ from a common epithelial cell? Is it always easy to distinguish between a sarcoma (round or spindle cell) and granulation tissue? Is there not a close affinity between tumour growth and repair? In what case of malignant tumour can one definitely exclude injury or irritation?

Lorrain Smith, in his suggestive booklet *Growth*, speaks at length on "controlled" growth and "controlled" repair. Is repair, as we recognize it, always controlled? In the majority of cases a cut is repaired by a scar: just enough scar tissue is produced, no more—controlled repair. Occasionally, especially in negroes, a scar is not controlled: result, a keloid. An epithelial surface is damaged: in most cases the damage is repaired by just about the amount lost by damage—controlled repair. Sometimes, when the irritation is long continued, repair becomes uncontrolled—result,

a cancer. The same process obtains in injury to connective tissue. Normally, granulation tissue is produced and strictly limited in quantity to the need of the part; later it "fulfils its ultimate developmental intention" and a cicatrix is formed—controlled repair. Occasionally the formation of granulation tissue is uncontrolled, or the growth of certain round or spindle cells therein is uncontrolled—result, a sarcoma. Why, then, call in bacteria or a virus to account for tumour formation and not for ordinary repair?

Adami defined inflammation as "the local attempt of repair of a tissue"; if asked to define "repair" more clearly, can it be doubted that he would have said "controlled repair"? Why not define a tumour as "the uncontrolled attempt at repair in a tissue"? How does growth become uncontrolled? How does it become controlled in ordinary growth or repair? Here is heresy; can orthodoxy suggest better?—I am, etc.,

Department of Pathology, University
College, Cork, January 23rd

A. E. MOORE.

SIR,—The controversy that periodically rages over the relative merits of clinical and experimental methods in cancer research will be settled only when the problem is finally solved and we, or our descendants, can review impartially the part played by the several branches of medical science in overcoming this scourge.

Mr. Hastings Gilford, in his letter in the *Journal* of January 20th (p. 121), challenges in a general way the value of experimental cancer research and all the positive data it has produced. The discovery of carcinogenic substances, their isolation, and the possibility of recognizing them in, and eliminating them from, oils in commercial use apparently has no significance in connexion with human cancer. Admittedly occupational cancer represents only a small fraction of human cancer, and the protection of those engaged in dangerous occupations does little to reduce the appalling annual death roll due to cancer; but the failure of experimental workers to solve all the problems associated with malignant disease does not constitute a new problem. No one, not even the most successful surgeon, can claim a record of uninterrupted success, and even if experimental workers have not achieved the success that Mr. Gilford had anticipated, that does not justify his accusation of a "record of hard work, great ingenuity, and unbroken failure."

Clearly, in tackling such a problem as this, it is idle to demand success within a time-limit. If Mr. Gilford disapproves of our experimental methods what alternative does he suggest? Why should he object if experimental work offers no support to theories that could only be useful as a basis for investigation? Surely all serious students of cancer, be they clinicians or laboratory workers, are actuated by the same motive—the collection of accurate data bearing on all aspects of the disease. If the immediate utility of some experimental investigations is not obvious to all, we should at least give the writers the benefit of the doubt and assume that they are pursuing a definite line of thought, though I admit that it is sometimes difficult to guess what it can be.

In view of his extreme pessimism about experimental research it would be of considerable interest to know what leads Mr. Gilford to anticipate "that the great central problem of cancer, no longer obscured or made difficult by the clouds and winds of useless controversy, will then not only be clearly seen, but will be attacked with far better prospects of success," if only the research worker will cease to concern himself with human tumours, leave the field clear to—whom?—I am, etc.,

Feb. 3, 1934.

University College, London.

The Tuberculosis Problem

SIR,—The recent 'spate' of correspondence on this problem in your columns, culminating in Dr. Gordon Tippet's letter and quotation from a county medical officer of health's sad report on January 13th, surely, shows that something is wrong with our anti-tuberculosis campaign. Whose is the fault that cases are not recognized or sent for treatment until so advanced? Presumably an old scapegoat, the G.P., will be indicted by most; for do not the authorities provide tuberculosis dispensaries and sanatoria staffed by (presumably) specialists? Meanwhile the G.P., floundering amidst the various advices to pasteurize, not to pasteurize, to use and not to use tuberculin, et cetera, and armed with a stethoscope, a little common sense, and perhaps with the help of a municipal laboratory and a hospital's out-patient department, struggles on with the endeavour to obtain early diagnosis and early treatment for cases of consumption.

Are these local specialist tuberculosis centres rendering all the assistance possible? Consultation with some G.P. colleagues confirms the impression that, in this district at any rate, the dispensary dispenses with the use of x rays, tuberculin, more than one sputum examination (done in the local municipal laboratory and not in the clinic), and even suspicion of any history, signs, or symptoms, except a positive sputum. Suspected early cases are referred for advice, the specialist makes a few peremptory dabs at their chests with fingers and stethoscope, and they are usually returned with a chit marked "No evidence of tuberculosis." Many of these folk are then diagnosed at a hospital, notified, and again sent to the dispensary for advice on treatment. They are told to attend quarterly or perhaps monthly, but their names are not entered for institutional treatment until they become emaciated and pyrexial, owing to economic stress preventing adequate treatment at home. There is even then usually not less than six weeks' wait before admission. When these patients come out of the sanatorium they complain about the draughts (fresh air) and poor food, though regrettably they can never be persuaded to put these complaints into writing. The attitude of the clinic to the possibility of relapse in such patients is similarly ostrich-like.

Now by way of some constructive criticism, here are a few practical questions which arise:

1. How many such organizations are as inefficient as ours? I am hopeful that replies to this letter will prove—none. The facts will then be represented to the appropriate authority.
2. Is there any system of inspection of such organizations, and is any attempt made to keep them well equipped and to standardize their functions?
3. Can any tuberculosis clinic afford to spurn the use of (a) repeated sputum examinations, (b) an x-ray apparatus, (c) careful and repeated clinical examination, and (d) tuberculin, especially in the case of children, as aids to early diagnosis?
4. Should not such organizations be competent and instructed to advise individual treatment, either by a written pamphlet to the patient direct or to the G.P. in charge of the case, if any?
5. Finally, tuberculosis being a notifiable and presumably "infectious" disease, cannot steps be taken to lessen the interval before isolation and institutional treatment?

This letter is not intended as a personal attack on the local tuberculosis medical officer, but upon the system (or rather lack of it) which allows such a parody of scientific organization against the scourge. I shall be delighted to correspond and co-operate with any fellow G.P. who holds similar views, but in order not to shock any lay readers living locally who may chance to see the *Journal* I must sign myself anonymously

A. R. F.

January 17th.

Artificial Pneumothorax for Tuberculous Children

SIR,—In the *Journal* of January 6th (p. 14) Dr. William Stobie describes the treatment of three cases of pulmonary tuberculosis in children by artificial pneumothorax. The ages of his cases were 9, 12, and 15 years respectively. It will perhaps be of interest to him, as well as to your other readers, to know that, since the beginning of 1926, 132 cases of pulmonary tuberculosis in children were treated by this method at High Wood Hospital. At the time of the induction of the pneumothorax fifteen of these cases were below the age of 10 years, and the rest were between the ages of 10 and 15. In the youngest case the initial fill of air was given at the age of 4 years.

We do not, however, make any claims to originality in this matter, as many workers on the Continent have practised collapse therapy in children younger than ours at High Wood. Armand-Delille¹ describes 120 cases of pulmonary tuberculosis in infancy treated in this way, and although he does not state the exact ages of his cases here, in an earlier publication² he describes two cases aged 14 months and 1 year. But even this is not the last word on the subject, for as early as 1914 Billon is stated to have induced an artificial pneumothorax on a baby only 9 months old.—I am, etc.,

A. G. L. READE,
High Wood Hospital for Children,
Brentwood, Jan. 22nd. Medical Superintendent.

Control of Metastases in Breast Cancer

SIR,—Dr. Annis, while in general agreement with the views expressed in my letter of January 6th, nevertheless thinks that I am "too readily belittling the value of the time, labour, and, especially, money, which has been spent upon cancer research work under very distinguished auspices in this and other countries—with far too little result, I admit . . . but still surely with some." Now the point of my letter was that, since the days of Tut-ankh-Amen, practically no progress had been made in prevention of metastases. Research has been concentrated largely upon what may be called the cytology of cancer. Much has been added to our knowledge in this respect, and time, labour, and money spent upon the acquisition of fresh knowledge is never wasted. A recognition of this truth should not blind us to the fact that little has so far been discovered which can at the present moment be applied in practice.

The question of the prevention of metastases is obviously connected with that of susceptibility. Let us see what one of our leading research workers, Dr. Cramer, has to say on this subject (*Lancet*, January 6th, 1934, p. 104):

"If it [susceptibility] could be diminished, it would offer another method for the prevention of cancer. . . . I have carried out experiments with that object in view over several years, but as yet with no result. There is, however, experimental evidence that this factor can be increased by the administration of liver. . . . Unfortunately this change is in the wrong direction, but at any rate it suggests the possibility that by other means a change in the right direction might be brought about."

There is at present no drug or gland treatment which can be counted upon to reduce susceptibility: or, to put it in another way, to raise resistance. On the other hand, there is evidence, both clinical and experimental, to show that certain forms of generalized radiation can prolong life in cancer subjects, and that established metastases can be held in check in a small percentage of cases for

¹ *Rev. de la Tuberc.*, June, 1932.

² *Soc. Méd. des Hôp.*, June, 1927.

several years. The generalized x-ray treatment, briefly mentioned in my letter as a means of controlling metastases, is at present empirical.

What is badly needed is some laboratory test which will tell us when latent cancer is likely to become active, so that we may forestall it. Work in this direction is being carried out. The ultimate weapon against metastases may be something far removed from radiotherapy of any kind; but meanwhile it is better to use an empirical method which has had some successes to its credit than to sit with folded hands waiting for manifestations of distant invasion, which in a large proportion of cases are bound to occur.—I am, etc.,

S. GILBERT SCOTT.

London, W.1, Jan. 24th.

Raised Intraocular Tension

SIR,—In your issue of January 20th Flight Lieutenant R. L. Raymond describes a new symptom-complex of increased intraocular tension and frontal headaches in young persons. He draws his conclusions from four cases; but, apart from an ophthalmological point of view, the evidence which he gives is not sufficient to support the diagnosis of raised intraocular tension. Apparently the author based his diagnosis of increased tension on digital tonometry, confirmed in one case by a shallow anterior chamber in another by cupping of the optic disk, and corroborated in all by tenderness of the eye and the abolition of all symptoms on exhibiting eserine. The remainder of the evidence is negative.

On the above positive evidence the following observations may be made without going too much into detail. Digital tonometry is of great value when definite alterations of intraocular pressure are present. It is, however, unsafe to base a diagnosis on it in doubtful cases, and some doubt appears to have existed in Dr. Raymond's mind, as he states that the tension was "thought to be higher" on digital examination. One of the cases was thought to have a slightly shallower anterior chamber in the affected eye; but it must be pointed out that it is difficult to compare depths of anterior chambers when the pupils are of different size. In the case quoted the pupil of the affected eye was constricted by eserine, and the anterior chamber in such an eye usually appears shallower, quite apart from the question of raised pressure, merely because there is a larger area of iris in evidence. Another case was stated to have an optic disk which was slightly more cupped in the affected eye, but which was normal on examination five weeks later, after treatment with eserine. This is remarkable evidence, as no treatment has yet been known to remove cupping of the optic disk. Tenderness of the eyeball is no evidence of glaucoma, and may merely be associated with the headache. The therapeutic test of the effect of eserine is not easily put to one side, but the instillation of distilled water has often done much to relieve pain which has not been shown to have an organic basis.

I do not question the accuracy of Dr. Raymond's clinical observations, but I feel that he has attached undue importance to some relatively insignificant details which cannot be regarded as of diagnostic import. However, no one should place any reliance whatever on digital tonometry which has not been confirmed by a more accurate method of tonometry, unless it is possible to say that the intraocular pressure is raised beyond all shadow of doubt, and then, of course, there would be other indubitable signs of glaucoma. In any case glaucoma can, and not infrequently does, occur in young persons of all ages, and the pain may be referred to the frontal region.—I am, etc.,

London, Jan. 24th.

VICTOR B. FURVIE.

"Cheap Anaesthesia"

SIR,—In the daily Press there is an account of an inquest at which an eminent pathologist is reported to have stated that open ether is the safest anaesthetic. I do not want to criticize in any way the case out of which this comment arose. I know nothing about it except that it was a bad risk. Besides, deaths on the table may happen to anyone; I freely admit that my own record is not free from them. But it is not apparent why a pathologist, whose opinion in his own department is no doubt most valuable and reliable, should make dogmatic statements about anaesthetics, on which subject he is about as likely to be correct as an anaesthetist who pontificates on pathology.

The pathologist in question, in thus retaining an opinion ten years out of date, has apparently never heard of gas and oxygen or ethylene and oxygen. The former is certainly and the latter probably far less toxic. He also omitted to mention the undoubted facts that open ether is the most unpleasant method known from the patient's point of view, and that its popularity is largely due to its apparent ease of administration and the strange mentality of surgeons who demand exorbitant fees for themselves and yet cheerfully risk their patients' comfort and safety by insisting on cheap anaesthesia.

The astounding lethargy with which the art of anaesthesia is regarded in many districts, an attitude of mind which assumes that nineteenth century methods are good enough for twentieth century work and that no improvement is desirable or possible, makes me think it high time the whole subject was ventilated.—I am, etc.,

Morley, nr Leeds, Jan. 24th.

W. STANLEY SYKES.

Local Anaesthesia in Midwifery

SIR,—Infiltration of the perineum with a suitable local anaesthetic, during the second stage of labour, has its advantages, and although I do not suggest that this is anything new, yet it does not appear to be very much employed. By combining it with very light anaesthesia from a Junker's inhaler a normal labour can be rendered sufficiently free from pain at this stage without the disadvantage of rendering the patient incapable of helping herself and taking "the lick" out of the uterine muscle. The general condition of the patient, both mental and physical, after this method, is better than when more general anaesthetic is given. If perineal stitches or division of the perineum is required this can be done painlessly without any more general anaesthetic. An anaesthesia with gas and oxygen is not easily arranged for, and this method is so simple and harmless. The agonizing pain of the stretching and tearing of the perineum is abolished and the worst of the pain is eliminated.

It is specially applicable in the case of a primipara or in a breech delivery, when a painless perineotomy can be performed which improves the child's chance by facilitating the delivery of the after-coming head and relieving pressure on the cord. Perineal examination and suturing afterwards can be done more easily, as the patient does not contract her thighs when touched.

The method advocated is to wait until there is some bulging of the perineum, and then to inject, with a fine hypodermic needle on either side of the midline of the perineum, half-way between the anus and the external edge of the perineum, about 2 ccm. of paraffin or 1 ccm. of the amputol on either side of the perineum. Paraffin "oil" is satisfactory, as it can be used in each delivery as and is conveniently put up in 5.5 ccm. ampoules (1 in 1,000), and in these doses is harmless and efficient.

After this method the perineal incision heals quickly and cleanly, bruising having been avoided. I often find that the patient can give all the anaesthetic necessary herself or assisted by the nurse; and the obstetrician can confine his attention without interruption to the birth and give his instructions to a patient who is not "out of control" from pain.—I am, etc.,

Pruritus Ani

SIR,—I should like to endorse Dr. Hernaman-Johnson's views (*Journal*, January 20th, p. 123) on the treatment of pruritus ani. In his letter he states that in the majority of cases of this troublesome disorder surgical treatment is quite unnecessary. It is my practice in these cases always to make a rectal examination, and should there be any evidence of piles, fissure, or other abnormalities, these must of course be treated. The importance of making such an examination cannot be overestimated. Examination is also made for the presence of worms, which are sometimes responsible for the condition.

The skin is usually lichenified and excoriated as a result of scratching—and in places may be denuded of epithelium.

With regard to treatment, any raw areas should be painted with a 2 per cent. solution of silver nitrate. Four doses of 1/3 B unfiltered x rays are given at intervals of ten days, and an antipruritic ointment is prescribed. In most cases the patient begins to feel some relief after the second treatment, and it is advisable to warn him not to expect any improvement until then. At the end of the course of treatment most patients are completely relieved and do not need to use any antipruritic applications. The cessation of irritation and the return of undisturbed sleep at night soon lead to a marked improvement in the patient's general condition.—I am, etc.,

NORMAN BURGESS, M.D., M.R.C.P.

Clifton, Bristol, Jan. 23rd.

SIR,—In his very interesting letter in your issue of January 20th, Dr. Hernaman-Johnson falls into the common error of writing on pruritus ani as if it were a disease *sui generis*, and of referring to it as being "curable" by the application of x rays. A certain amount of unnecessary mystery surrounds pruritus ani, which is not the case with other skin irritations. Pruritus ani is a mere symptom of very numerous rectal abnormalities. It is perfectly true that temporary relief may be afforded by various forms of treatment—for example, subcutaneous injections of A.B.A., Ball's operation, or—as Dr. Hernaman-Johnson writes—by x-ray treatment. All of these, however, act merely by rendering the skin of the anal region anaesthetic or more healthy for a longer or shorter period. It can only happen rarely that such relief proves permanent, because all of these treatments overlook the underlying cause—whatever it may be in each individual case.

The causes of pruritus are numerous, and it is impossible in a letter of reasonable length to enumerate them fully and to describe the treatment appropriate to each. To show the fallacy of applying treatment to the skin only it is sufficient to mention that one of the common causes of severe and intractable pruritus is, as Colonel W. P. Macarthur pointed out in the *British Medical Journal* of August 22nd, 1931, the presence in the bowel of the *Enterobius vermicularis*—a parasite resembling the thread-worm of children. A large proportion of cases of pruritus can be shown to be due to this cause. Once this fact

has been admitted, the fallacy of writing as a "cure" of any application to the skin alone of remedies such as x rays, injections of A.B.A., or anything else, becomes obvious. They undoubtedly may give temporary relief, but until the parasites have been destroyed no permanent "cure" of the irritation can be expected.

Among other common causes of pruritus are internal haemorrhoids, chronic proctitis, inflamed anal crypts, submucous tracks, etc. To effect a permanent relief of pruritus each case must be fully investigated by an expert proctologist and the cause found and dealt with. Only in the cases in which a painstaking search for a cause has failed should local anaesthetic remedies or x rays be tried. In my opinion too many of these cases are referred to dermatologists instead of to proctologists. The cause of pruritus is a rectal one in the very great majority of cases, and it is as useless to send a case of pruritus ani to a skin specialist instead of to a proctologist as it is to send a case of neuralgia due to a carious tooth to a neurologist instead of to a dentist. In both cases temporary relief may be given, but no permanent "cure" can be expected until the cause has been found and removed.

Dr. Hernaman-Johnson also writes that cases of pruritus "associated with severe piles will, of course, require operation." I have been trying for the past eighteen years or so (latterly with considerable success) to convince the profession that most cases of internal haemorrhoids—even very severe ones—can be treated successfully without operation by means of injection. In no class of case are the results more satisfactory than in those in which intolerable pruritus is a symptom. The cases in question are by no means always those in which the haemorrhoids are unusually large. It must be remembered, however, that it does not follow that because a patient with pruritus has haemorrhoids there may not be other rectal abnormalities present also. Relief will be permanent only if all the rectal abnormalities which are present are dealt with effectually.—I am, etc.,

London, W.1, Jan. 26th.

ARTHUR S. MORLEY.

Left-sided Stance for Urethral Instrumentation

SIR,—I have been much interested in Mr. Neve's description of litholapaxy simplified (*Journal*, December 30th, 1933, p. 1211) and the subsequent correspondence on left-sided stance for urethral instrumentation in your issues of January 13th and 20th (pp. 78, 124).

I am right-handed, and as a student learnt to stand on the left side of the patient for passing urethral catheters and bougies, but after doing many cases of litholapaxy by standing on the right side of the patient I developed a sense of touch for urethral instrumentation. Hence the right-sided stance is adopted by me in all these cases except in perineal litholapaxy, when the patient is in the lithotomy position and I in the median position. I may here state that I have found the best urethral bougie to be a lithotrite. I have, with the aid of the weight of the lithotrite plus the sense of touch for the passing of urethral instruments, succeeded in passing through most, if not all, strictures, and when more than a false passage was present. Another big advantage of the lithotrite as a bougie is that, after passing through a stricture and before withdrawal, the blades can, if necessary, be separated sufficiently to stretch the tissues in the stricture without tearing the mucous membrane of the urethra.—I am, etc.,

C. C. MURISON, F.R.C.S. Ed.,
Colonel I.M.S. (ret.).

Knocke-Zonle, Belgium, Jan. 20th

SIR.—If Dr. Browdy (*Journal*, January 20th, p. 124) is referring to the method by which the passage of a curved metal urethral instrument is commenced by holding it parallel to Poupart's ligament of the left side, certainly, by standing on the left side, one avoids awkwardly reaching over the patient and crossing the hands at the beginning of the manoeuvre. But, at the end, there is an awkward "backhand" use of the right hand, unless, as described and illustrated by one authority, the hands are changed during the manoeuvre. It is, however, better to keep one hand entirely for holding the penis and the other for the instrument.

Again, most couches are placed so that the patient's left side is against a wall. But, even if both sides are accessible, it involves unnecessary exercise—for instance, in a stricture clinic—to stand on the left when passing a metal instrument and on the right when passing a soft one, as recommended by one textbook.

These disadvantages of the left-sided stance are avoidable if the operator always stands on the right for urethral instrumentation, as is the routine practice of the leading exponents of the art whom I have seen. Curved metal instruments are then best passed by the so-called "tour de maître," in which the concavity of the curve at first faces downwards, and the point of the instrument presses towards the floor of the anterior urethra, thus minimizing the small risk of catching the point in the lacuna magna or other orifice in the urethral roof. There is then no awkward crossing of the hands, no needless changing of them in the middle of the manoeuvre, and no unnecessary jumping about from side to side of the couch.—I am, etc.,

London, W.1, Jan. 23rd.

ALEX. E. ROCHE.

Vision of Brightness and Colour

SIR.—The address of Professor J. S. Haldane to the Royal Medical Society of Edinburgh not only strikingly shows the inability of hitherto current doctrine to explain the facts which he gives, but also the need to examine certain fundamental physiological doctrines. Tradition has handed down to us the idea that retinal end-organs are structures which are quiescent until excited to activity by light. This, however, is not a scientific theory, for there never was a time when anyone put together the facts of retinal stimulation and deduced therefrom that those organs are quiescent until excited, just as are the members of the excised muscle-nerve preparation. None, moreover, could so do, because every retinal phenomenon observed requires a special hypothesis to explain away the fact that retinal behaviour is never what it ought to be if the end-organs were of this type. The current physiology of retinal stimulation is a mass of such special hypotheses which are not required by the facts themselves but by the attempts to bring these facts into line with a preconceived notion that retinal end-organs are quiescent until excited.

Actually, some of the modern work on muscle and nerve provides the renitent evidence against this fundamental theory. We now know that the responses of structures, such as retinal organs have been presumed to be, are "all or nothing." It is possible to account for a grading of response in living muscle by imagining that the organ works fractionally, with each fraction always doing its utmost; but such an hypothesis cannot be applied to the eye because the size of a retinal picture, and with it the number of end-organs involved, is independent of the brightness of the light. If, then, this fundamental hypothesis were correct, our vision could be only of dazzling brightness or inky blackness, and the only picture we could see would be areas of those two states.

Nothing, however, could be more typical of the

behaviour of a rhythmically active structure than a capacity to give responses, as augmentations, which are graded according to the strength of the stimulant. Our capacity to perceive differences of light and shade constitutes, in fact, part of the evidence that retinal end-organs have an inherent rhythmical activity which is augmented by light. The other features of retinal stimulation all fall into line with this. The proposition of stimulating a rhythmical organ to greater activity is, however, as different from that of exciting a quiescent one as is the sparking of gases in a motor different from the proposition of getting more power out of the machine after it has begun to tick over. But physiologists, in their past studies of excitability, did the equivalent of studying the laws which govern the sparking of gases, and imagined that these laws were applicable to throttle adjustments.

The capacity of a rhythmical tissue to have its activity modified by environmental change has been called "responsiveness" and its laws studied. Furnished with a knowledge of these laws, Professor Haldane, instead of presenting his audience with a puzzle in his crossed shadow experiment, could have informed them that it was a predictable phenomenon. The puzzle was provided by the assumption that this was a phenomenon of excitability. In addition, one may further predict that what Professor Haldane seems to have looked for will probably be seen if he keeps his gaze accurately fixed for some five or ten minutes—the time will vary according to the previous history of the seeing eye. A further predictable phenomenon, on the basis that retinal end-organs have rhythm, is that the eye of a miner at the coal face will be more responsive to light than it is at the surface. The actual hundred-thousand-fold increase may not be predictable, but nevertheless is not surprising, a million-fold having been found in hearts. Alternatively, when one possesses an adequate knowledge of the properties of rhythmical tissues, these facts concerning the miner's eye provide part of the evidence that retinal end-organs have an inherent rhythmical activity.

It would probably take up too much of your space to discuss in detail Professor Haldane's experiments on colour vision. I may, however, be permitted to point that, on the basis of retinal rhythm, the apparent existence of four primary colours, arranged as Hering arranged them, is predictable. There is also no difficulty in accounting for the fact that others have found only three. The current difficulties concerning colour-blindness also have an automatic solution. An undamped rhythmical or vibrating system provides all the possibilities that Professor Haldane finds but cannot account for on the basis of the theories hitherto current. His facts constitute, indeed, cogent evidence against them, but, like their authors, Professor Haldane has not been able to get away from that fundamental error of presumption, quiescence. He has therefore been constrained to act as they did—namely, to produce still another hypothesis, which attempts to weld the facts into accord with a preconceived notion.

In contrast with this I have dealt primarily with questions of fact. The existence of responsiveness and its laws, for example, are not only questions of fact, but also they are capable of verification by anyone who cares to look. The existence of an inherent retinal end-organ rhythm is admittedly a theory, but nevertheless it is directly derived from the facts, and stands the test of a capacity for accurate prediction. But its derivation and the making of predictions requires more knowledge of the properties of rhythmical tissues than some physiologists seem to possess. The necessary more is admittedly new knowledge, but it consists of facts.—I am, etc.,

"Under the Influence of Drink"

SIR.—Professor C. R. Marshall's letter will be of interest to the general public as well as to the medical profession. One must cordially agree with his statement, "If it were possible to get a proper perspective into the public mind regarding the action of alcohol something might be gained."

There are three points upon which attention should be focused. They are: (1) It is not the amount of alcohol imbibed, but the percentage of alcohol circulating in the blood at any given time, which produces the signs and symptoms of being "under the influence of drink." (2) The amount absorbed does not necessarily bear a proportional relationship to the amount taken into the stomach. (3) The percentage of circulating alcohol which produces signs and symptoms of intoxication is quite small: (a) "slight" intoxication with 0.1 per cent.; (b) "marked" intoxication with 0.25 per cent.; (c) "grave" intoxication with 0.3 per cent.; (d) "coma" with 0.35 per cent.; (e) "death" with 0.4 per cent. From this it is to be recognized that 0.1 per cent. of circulating alcohol will very sensibly affect any action requiring only a second for judgement. The suggestion made by Professor Marshall that a competent body should carry out large-scale experiments is overdue, and should be put in hand forthwith.

May I venture to suggest a form of the "simple, cheap, and foolproof apparatus," less elaborate than Miles's pursuit-meter, which could be kept at the police station for the use of the police surgeon when called upon to test a person suspected of being under the influence of drink. The apparatus consists of three buttons placed vertically, and coloured from above downwards green, amber, and red (the reverse order of traffic signal lights). The subject is asked to press one of these buttons, and, at the same time, by means of an electrical connexion, his judgement as to selection would be recorded. If the reaction was markedly delayed it would be suspicious. If, on a repetition of this test, the time taken was longer than the average for a non-alcoholic subject, it would be confirmation. Such a test, plus an accurate determination of the alcohol-blood content, which can be obtained from 0.2 c.cm. of the patient's blood withdrawn into and sealed within a capillary tube forthwith, should be sufficient, it would seem, to give a statement on oath as to whether or not a person was under the influence of drink so as to be incapable of proper control of a car.—I am, etc.,

Woodbridge, Jan. 27th.

H. K. V. SOLTAU.

Painful Injections

SIR.—I have been much interested in the observations made about painful injections, in reply to my letter published in the *Journal* of January 13th (p. 76). I do not wish to be accused of hair-splitting, but, in answer to Dr. Loewy (January 20th, p. 124), I should like to point out that his method depends on evaporating the ether from his syringe "by means of aspirating air repeatedly." It has the disadvantage that, outside a sterilizing plant, sterile air does not exist, and some day one might be unlucky enough to aspirate some pathogenic spores which were not killed by the ether. I think Dr. Castleden (January 27th, p. 172) is nearer the mark with his antiseptic solution, "provided that he is lucky enough to have sterile cooled water always handy to wash out the solution." If he uses ether his method is open to the same objection as that which I raised to Dr. Loewy's method. Personally, I never use anything but all-glass syringes, which I have not found to warp if boiled from the cold. Also, using rustless steel needles, I have not found these to become blunt from repeated boiling. As

regards Dr. Loewy's remarks—that boiling leaves water in the syringe, and that measurements of injections are thereby faulty—I should like to point out that a good syringe empties practically every drop of fluid. All that it does not expel it does not deliver! It is therefore wise to buy syringes that do empty themselves, in which case the objection disappears. Dr. Durrans's observations (January 27th, p. 172) on avascular areas have interested me greatly, and I am going to attempt to confirm them.

May I, in conclusion, make a practical suggestion? A number of years ago the research workers of Messrs. Burroughs and Wellcome gave me a very useful tip. Most glass syringes have a flange at the top. It is easy to find glass test tubes of various sizes which allow the syringe to drop into the tube as far as the flange. The syringe, with needle in position, can be boiled together with the tube, drained, and a sterile lint wrapping with a rubber band then placed over the top until the syringe is required for use. During work the tube can be laid on the edge of a table, and if it is desired to place the syringe down for a moment a sterile receptacle is waiting. Most practitioners could afford to keep two or three syringes thus prepared to carry round, and the daily preparation of these is easily effected in odd moments.

I still maintain that boiling in distilled water is the best method of sterilizing any all-glass syringe (and I use no other sort), and the possession of several of these overcomes the necessity of rapid and unsatisfactory sterilization for the next patient. I should be pleased to give particulars of the syringes and tubes which have proved satisfactory to anyone who is interested.—I am, etc.,

London, S.E.5, Jan. 28th.

GUY BOUSFIELD, M.D. Lond.

SIR.—May I add another note to the "painful injections" series?

Select a spot of skin free from a hair follicle, for if the needle is thrust through one of these it will be likely to "tickle up" the associated sensory nerve ending. As to injections with spirit in or on the needle, I personally have received several of them, and should like to record that the result is a sensation not unlike being stung by a wasp!—I am, etc.,

Findon, Sussex, Jan. 28th.

W. R. E. HARRISON.

SIR.—The site of an injection should certainly be observed closely in a good light, as Dr. Durrans suggests (*Journal*, January 27th, p. 172). It will then be easy to avoid the hair follicles when inserting the needle. As we know from attempts in removing adhesive plaster, the hair follicles are most sensitive to pain.—I am, etc.,

London, W.1, Jan. 28th.

F. E. LOEWY.

Continuous Intravenous Saline

SIR.—I am glad to learn that Sir William Coates, who antedated me by a year in his post as obstetric assistant, anticipated me by several years in using intravenous injection of fluid for the treatment of post-partum haemorrhage. But I would point out that my paper (eight cases) was on the intravenous injection of normal saline fluid, in large quantity (25 to 40 ounces), repeated if necessary. This repetition the continuous method of Bailey and Carnow obviates. Of Sir William Coates's two cases, in one not saline but "about 22 ounces of simply warm water" was the fluid injected; in the other an unstated quantity of Jennings's solution, which contained five salts and alcohol (Jennings himself injected 16 ounces). The reasons for using normal saline and for increasing the quantity injected will be found in my paper, which also

refers to a previous case of intra-arterial injection for post-partum haemorrhage.

As a historian I cannot but be pleased if it can be shown that I have been anticipated, either in the employment of larger quantities (up to 40 ounces) of normal saline or in the provision of sealed glass tubes containing two drachms of sodium chloride in sterilized solution from which to make it (see my letter in the *Journal*, January 13th, p. 75).—I am, etc.,

London, W., Jan. 27th.

HERBERT R. SPENCER.

A Falling Birth Rate

SIR,—I note that the birth rate in England and Wales for 1933 has fallen to the lowest level on record—14.4 per thousand of the population. It is useful to remember that (assuming, as I am doing in this letter, emigration and immigration to balance one another and the national [= average] expectation of life to remain constant) the birth rate needful to ensure a stationary population in a nation is one thousand divided by the national expectation of life—that is, supposing the expectation of England and Wales to be 56 years, the birth rate necessary to ensure and maintain a stationary population in that region would be $1,000 \div 56 = 17\frac{7}{8}$. So long as the birth rate is above that necessary to produce a stationary population, the population will continue to increase year by year and the younger members will outnumber the older. If, in a country with such a birth rate, the birth rate falls to the level needful to produce a stationary population but no further, the population, owing to the excess of young members, will not at once begin to decline, but the yearly increment will begin to decline year by year, until finally the population remains at a dead level, neither increasing nor diminishing from year to year. Should, however, the birth rate fall, as it has done in England and Wales, below the figure necessary to produce a stationary population—that is, from $17\frac{7}{8}$ to $14\frac{4}{10}$ —there necessarily ensues, not only (a) a rapid fall in the yearly increment until the level is reached at which births and deaths equal one another, but (b) a rapid yearly decline in the population after this stage is reached, which, should the process continue long enough, will ultimately lead to extinction.

A diminution of the population of this country by, say, two millions, might have its advantages, but what of the vacant spaces in the Empire? I understand the Japanese are increasing at the rate of a million annually.

How do these considerations concern us as a profession? It is highly probable that the birth rate will continue to fall below the record figure 14.4, because the lowest social grades are still largely ignorant of contraceptive measures. Does it not seem that, from the standpoint of eugenics and imperial welfare, we should do our utmost to check the falling birth rate among the most desirable while encouraging it among the least desirable?—I am, etc.,

London, W., Jan. 28th.

HARRY CAMPBELL.

Hereditary Blindness

SIR,—If Mr. Myles Bickerton has the prevention of blindness at heart it is hard to see how his contribution headed "The Menace of Hereditary Blindness" is going to help this cause. Surely we have got past the stage when highly coloured and even inaccurate statements can be accepted. For example, his notes on the figures in Table I would lead one to believe that there is a steady annual increase of blindness, whereas it is generally recognized that the rise in numbers is almost entirely one of registration, because registration now brings benefits to the blind which were not available in 1919.

My own small experience as certifier for the Plymouth City Corporation proves this, as there is a steady drop in the number that I examine per annum, due to the fact that I have almost wiped off a large list of persons who applied as they became aware of the benefits they could get. Why does he stop at the figure of 250,000, which he suggests as a possible total? Any other figure might be just as accurate, especially as he includes categories 3, 4, and 5 and ignores all the certificated cases undergoing training or receiving necessitous grants in addition to their pensions. On going over his paper there are so many questionable points that it would need a whole issue of the *Journal* to hold a paper refuting them.

I would, however, like to know how 1 in 15 of senile cataracts can be prevented (Table II), or how—short of forbidding marriage to any person with a myopic history—he would prevent all the cases of blindness due to myopia. I have only got as far as the second out of twelve columns of Mr. Bickerton's paper, but I will skip on to the last column, which contains his possible remedies; of these, the first and last seem to me to be the only sensible suggestions, and those not even mainly for their influence on hereditary blindness.—I am, etc.,

Plymouth, Jan. 24th.

Cecil B. F. Tivy.

Comments in the Coroner's Court

SIR,—I entirely agree with the remarks of a consulting surgeon in the *Journal* of January 13th (p. 79) regarding comments by coroners, and I am prompted to record an experience that befell me some years ago when I held an appointment as honorary surgeon to a small hospital.

A patient was admitted into this hospital suffering from injuries as the result of a street accident. The house-surgeon telephoned to me and informed me of the admission. I was just going out to dinner, but offered to come to the hospital if necessary. He said that the man had concussion, and possibly a fractured base of the skull. He outlined the treatment he had adopted, and said he was not anxious about the patient. There was nothing to add to this treatment. During the evening I telephoned from my friend's house, and found that the house-surgeon had been out for the evening, but was expected back in a few minutes. I said that I should be where I was for another half-hour, and I gave the telephone number, asking that a message should be left for the house-surgeon on his return to telephone there if he wanted me to visit the hospital. I heard nothing more until the following day, when I was told that the patient was dead. The house-surgeon had tried the number I had given, but said he could not get a reply. He did not speak to the supervisor, nor did it occur to him to telephone to my house. My visit would have been merely a matter of form, as no treatment could have saved the patient, who died of a fracture of the base of the skull and intracranial damage to the base of his brain.

I was not interviewed by the coroner nor by any representative of his. I was not informed when the inquest was to be held. I was not called, or even advised to be present. Yet I was severely criticized in public, by name, by the coroner, who had formerly been in medical practice, and now aired such medical knowledge as he possessed. He talked rubbish about the possibilities of decompression operations in cases of fractured base, and so on. My complaint, however, is not with his flights of surgical fancy, but with his conduct of a legal inquiry in which he violated every principle of fair play. The house-surgeon avoided any censure by giving a sufficiently different tale to the one outlined above. I felt so strongly about the whole matter at the time that I wished to take it up; but my colleagues, while sympathizing with my sense of injury, persuaded me not to do so, lest the coroner might vent his spleen upon the hospital by a still further display of his power to inflict damage by unrestricted comments.—I am, etc.,

January 18th.

ANOTHER CONSULTING SURGEON.

Death Certification

SIR.—In view of the fact that there has been discussion from time to time as to the advisability of making it compulsory for a medical man to view the body before issuing a death certificate, the following experience of mine may be interesting.

One evening not long ago a man called for a death certificate for his mother, aged 91, whom I was attending, and who had last been visited three days earlier. There was no relative living in the house of the patient, and he was therefore first in succession of those entitled to have the certificate issued to them. Nevertheless, I refused on the grounds that he had not actually seen his mother since her alleged decease (a fact not volunteered by the man), and it is fortunate that I did so, for the following morning an occupant of the patient's house called, not for a certificate, but for a bottle of medicine for the lady in question!

Considering the age of the patient, and the fact that she was confined to bed with bronchitis, the evidence of the son might have been considered sufficient to justify the issue of a death certificate.—I am, etc.,

Kirkby-in-Ashfield, Jan. 25th.

J. D. DURANCE.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a congregation held on January 26th the following medical degrees were conferred:

M.B., B.CHIR.—G. W. Hall-Smith, N. M. James, J. Parkes.

M.B.—E. W. Price, A. H. Charles.

B.CHIR.—*T. M. Bell, J. S. Mitchell, W. E. Wells, S. M. Thompson, F. Clifton, R. H. Young.

*By proxy.

UNIVERSITY OF LONDON

At the meeting of the Senate on January 24th, with the Vice-Chancellor, Professor L. N. G. Filon, F.R.S., in the chair, G. P. Wright, D.M.Oxf., was appointed to the Sir William Dunn Chair of Pathology tenable at Guy's Hospital Medical School as from March 1st. Since 1931 Dr. Wright has been assistant lecturer in morbid anatomy and curator of the museum at University College Hospital Medical School, and also pathologist to the hospital. The title of Reader in Pathology in the University was conferred on Miss Joan M. Ross, M.D. (London (Royal Free Hospital) School of Medicine for Women).

British Post-Graduate Medical School

The Senate was informed that it was expected that the new British Post-Graduate Medical School would be opened to students in October next. The school buildings are at Hammersmith, adjoining the London County Council Hospital, with which it will be associated. In accordance with the terms of the Royal Charter the Governing Body of the school (of which the Right Hon. Sir Austen Chamberlain is the chairman) has applied for its recognition as a School of the University, and the Senate has, as a temporary measure, given it such recognition for a period of two years.

Lectures on Mental Deficiency

A course of lectures for medical practitioners on mental deficiency, including conditions allied to it, and problems connected with retarded and difficult children, supplemented by a course of clinical instruction, has been arranged by the University Extension and Tutorial Classes Council in co-operation with the Central Association for Mental Welfare during April. It will be divided into two parts: I. Mental Deficiency (April 16th to 21st). II. Retarded and Difficult Children (April 23rd to 28th). The whole course may be taken or Part I may be taken separately: Part II may be taken separately by medical practitioners who have attended Part I in previous years, or who have specialized experience approved for the purpose of this course. The course will be based on the requirements for the University of London diploma in psychological medicine, and is intended for qualified practitioners, more especially for those who are engaged as school medical officers, certifying officers to local authorities under the Mental Deficiency Acts, or as medical officers of institu-

tions, or who are otherwise definitely concerned with the care of subnormal or abnormal persons. The University will grant certificates of attendance to those who have attended regularly either part or both parts of the course, taking both theoretical and practical work. The course will be held only if enough applications are received to make it financially possible. All communications should be addressed to Miss Evelyn Fox, c/o University Extension Department, University of London, Imperial Institute Road, South Kensington, S.W.7.

Two advanced lectures in chemistry will be given at University College, London (Gower Street, W.C.) by Professor L. Ruzicka of Zürich on February 27th and March 1st, at 5.30 p.m. Lecture I will be on the many-membered carbon rings, Lecture II on the constitution of the sesquiterpenes and diterpenes. The lectures will be delivered in English; admission free, without ticket.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

A quarterly meeting of the Royal College of Physicians was held on January 25th, when the President, Lord Dawson of Penn, reported the valuable gift to the library of engraved portraits of medical men by Dr. Arnold Chaplin, and announced the award of the Swiney Prize for 1934 to Sir William Searle Holdsworth, K.C., Vinerian Professor of English Law in the University of Oxford.

Dr. G. F. Buchart was appointed, to represent the College at the congress of the Royal Sanitary Institute to be held in Bristol in July, and Dr. R. R. Trail as representative at the annual conference of the National Association for the Prevention of Tuberculosis in June.

A donation of 100 guineas was voted to the fund for the purchase of the Codex Sinaiticus.

Lectures

The following lectures will be delivered at the College: on February 27th and March 1st, at 5 p.m., the Milroy Lectures by Sir George Buchanan, C.B., on "International Co-operation in Public Health: its Achievements and Prospects"; on March 6th, 8th, and 13th, at 5 p.m., the Goulstonian Lectures by Professor E. C. Dodds, M.V.O., on "Hormones and their Chemical Relations"; on March 15th and 20th, at 5 p.m., the Lumenian Lectures by Dr. H. L. Tidy on "Glandular Fever and Infective Mononucleosis."

Membership

The following candidates, having satisfied the Censors' Board, were admitted Members of the College:

Jamshed Nasarvanji Bhada, M.B.Lond., Edward James Doome, M.B.Birm., Wilfrid Ingram Card, M.D.Lond., George Miller Clough, M.B.Sydney, Charles Richard Croft, M.D.Oxf., Amalananda Das, M.B.Calcutta, Charles Alban Gavan Duffy, M.D.Melb., George Ronald Ellis, M.D.Camb., Frank Scott Powweather, M.D.Liverp., Paul Ghaliongui, M.D.Cairo, Thomas Moore Greenaway, M.B.Sydney, Charles Herbert Stuart Harris, M.D.Lond., Elchon Hinden, M.B.Camb., William Hughes M.B.N.Z.U., John Henderson Hunt, M.B.Oxf., Renatus Keapthorne, L.R.C.P., John Parkes, L.R.C.P., Malcolm Henry MacKeith, M.D.Oxf., Douglas Gordon Radcliffe, M.B.Sydney, Max Leonard Rosenheim, M.B.Camb., Christopher Bagot Sangster, M.B.Adelade, Arthur Maurice Stewart-Wallace, M.B.Lond., Matthew Westwood, L.R.C.P.

Licences and Diplomas

Licences to practise physic were conferred upon the following 150 candidates (including twenty women) who have passed the final examination in medicine, surgery, and midwifery of the Conjoint Board, and have complied with the necessary by-laws:

S. B. Adams, S. H. Alavi, S. R. Ali, N. Asbell, H. H. Atkinson, J. S. Bailey, Louie M. M. Badnell, T. M. Bell, R. H. R. Beley, R. L. Benson, T. A. Best, I. S. Bhalla, Mary A. M. Bigby, E. W. Bitchcliffe, E. A. Bisson, C. J. F. Blumenthal, W. A. Bowdler, J. C. Buckley, P. G. Burgess, W. A. Cannell, F. F. Cartwright, T. Chandrasekharan, A. S. Cheong, M. M. D. Chughlall, R. H. Clark, C. W. J. Claydon, L. A. Collins, H. V. Corbett, Beryl D. Corner, Margaret C. Cox, C. S. V. Daniels, E. A. Danino, D. R. Davies, End S. Davies, L. W. Davies, W. A. Dawes, W. J. B. De Gruchy, C. J. D. Monte, D. P. Dewe, C. B. Dharmasena, T. H. Dias, W. L. Dove, Katharine E. M. Dunne, E. Dunshy, R. M. Ealand, G. D. ff. Edward, E. H. Evison, R. M. Farrington, Constance E. Field, W. T. J. Fowler, H. E. D. Gale, J. F. Gallaway, C. J. Gavey, C. A. George, S. S. B. Gilder, T. D. M. Gilles, J. G. A. Gilruth, C. H. Greening, I. H. Griffiths, R. M. Haines, S. Hales, H. C. A. Harris, P. S. T. Hutton, F. S. M. Higgs, R. Hill, G. T. Hindley, A. V. House, T. E. Howell, N. M. Jacoby, Elizabeth M. James, G. H. James, Joyce B. Jewson, R. W. John, D. J. Johnson, E. G. Jones, F. A. Jones, H. W. E. Jones, I. R. Jones, J. G. Jones, L. E. Jones, Ng K. Kai, Alice M. Kenn, I. K. Kerr, G. A. Kiloh, I. T. H. Knight, Mildred G. Latham, W. H. Gwladys R. Newlyn, Phyllis S. Lockie, L. Lurie, J. B. MacArthur, J. M. A. McArthur, J. W. Manser, R. Macarandis, W. N. MacK. Mason, L. H. Mattison, E. A. Mayston, Birlan G. Morton, R. B. Morton, G. A. Myers, R. V. N. Niyidra, D. H. E.

Oxford, R. S. Pachnanda, B. J. Philbin, J. Phillips, J. W. Piper, A. H. Pirie, J. D. Powell, Margaret H. Prentice, W. L. Price, H. S. Rassian, T. R. F. Raw, S. A. Razvi, D. C. Reavell, C. Reburn, C. W. D. Reeves, J. W. Rhys, J. D. Richardson, S. A. W. Rushbrooke, R. T. Rushton, M. F. P. Ryan, N. S. Sablin, H. S. K. Sainsbury, C. A. J. Sampson, P. H. Sandifer, B. I. Sanger, D. J. Sheehan, E. Shipman, A. Smith, M. C. L. Smith, O. C. Smith, L. Sobiya, A. B. Stenhouse, K. F. Stephens, D. L. McK. Stewart, A. A. J. Stolor, S. Sunkavally, R. J. C. Sutton, K. R. Tattersall, S. J. L. Taylor, R. E. Thomas, M. Tin, Beryl Twyman, G. R. Usmar, R. S. Vine, Winifred J. Wadge, S. H. Wass, D. Whittaker, M. E. Wigfield, Brenda Winterton, Sylvia V. F. Wolfe.

Diplomas in Public Health were granted, jointly with the Royal College of Surgeons, to the following:

S. S. Alam, S. S. Banker, D. G. Evans, W. H. Green, Rachel Halperin, A. N. Haworth, Victoria H. King, W. E. B. Lloyd, E. M. Lourie, G. P. McCarthy, J. G. Morgan, V. Nadamjah, R. C. F. Smith, T. H. Stephens, B. B. Wable.

Diplomas in Psychological Medicine, Laryngology and Otology, Tropical Medicine and Hygiene, and Medical Radiology were conferred jointly with the Royal College of Surgeons. The names of the successful candidates were printed in the report of the meeting of the Council of the Royal College of Surgeons published in our issue of January 20th (p. 130).

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—E. H. E. Cross, D. P. King, I. B. McCrae, H. Paroulakis, P. H. Wilcox.

MEDICINE.—E. C. Dax, E. G. Houghton, I. B. McCrae, S. Smith. **FORENSIC MEDICINE**.—T. Gardner, G. R. Greene, E. G. Houghton, H. R. Kasday, I. B. McCrae, R. M. Outfin, T. Sherman, D. Walton. **MIDWIFERY**.—F. G. S. Alderson, S. A. de Souza, H. O. Dole, J. C. Harvey, I. B. McCrae, J. R. Owen, H. Sobhi, H. M. R. Waddell.

The diploma of the Society has been granted to Messrs. T. Gardner, E. G. Houghton, I. B. McCrae, and S. A. de Souza.

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the requisite examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P. and S.Glas.:

Kate S. E. Muschamp, A. S. Russek, N. W. Nisbet, A. A. Crook, A. J. V. Klein, L. Krom, T. W. F. Gemmell, R. Ratnam, J. M. Dvca, A. S. Salama, J. W. D. Ferdinand, H. E. Schoen, A. B. Kabinick, Dorien Levine, J. A. Ratnayake, A. D. Macdonald, A. W. F. Catto, A. M. Chatelier, G. H. Taylor, S. Bedford, Mary R. McQuillan, H. Bogart, J. Weinberger, V. S. Inveda, I. C. Ostreicher, A. B. Johnson, M. J. Lowther.

Obituary

WILLIAM JAMES DOWLING, B.A., M.D. Trin. Dubl., assistant tuberculosis officer at the City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, died at the hospital, on January 24th, of pneumonia, at the age of 41. He was the second son of Thomas Dowling, district inspector of the Royal Irish Constabulary, and was educated at Rockwell College and Trinity College, Dublin. He was an exhibitioner in modern languages and Nutting scholar. Immediately after qualifying in 1915 he joined the Special Reserve of the R.A.M.C., and was on active service in France throughout the rest of the war. He served with the 3rd Division, and was stretcher bearer captain to the 42nd Field Ambulance and 3rd Battalion Machine Gun Corps. He was mentioned in dispatches by Lord French, and subsequently awarded the Military Cross with bar. After the armistice he served in Germany with the Army of Occupation, and represented the 3rd Division (acting as adjutant for a combatant corps, an unusual distinction for a non-combatant officer) in the march under the Arc de Triomphe in Paris. After the war he settled in practice in North London, and subsequently became medical officer to out-patients, and then assistant tuberculosis officer, at Victoria Park.

The death took place on January 12th at Sawbridge-worth, Herts, of **Dr. JOHN KENNEDY WILL**. He was born at Cullen, Banffshire, in 1857, and received his medical education at Aberdeen University, graduating M.B., C.M. in 1882, and proceeding M.D. in 1887. In 1884 he was appointed assistant medical officer to Bethnal House

Asylum, London, under the late Dr. John Miller, whom he succeeded as medical superintendent in 1886. Later he was appointed lecturer in mental diseases to the London Hospital, a position which he held until 1920, when the site of Bethnal House was sold to the local authorities in connexion with the housing scheme. After a visit to Ceylon, where he had family connexions, Dr. Will retired and lived at Sawbridgeworth. He married in 1889 Miss Ella Ring, and had a family of three sons and four daughters, all of whom, with the exception of one son who was killed in aerial combat in 1917, survive him. Dr. Lindley Scott writes: John Will's clear head and sound judgement made his advice much valued; firm enough he could be, but his gentleness and kind thought of others were very convincing. His hospitality at Bethnal House remained long in the recollection of many old students of the London. As a friend he was delightful, ever generous, full of anecdote, with a sporting instinct and a keen sense of humour that gave him unusual charm. To know him well was to love him well. He leaves a gap in one's friendship very difficult to fill.

We regret to announce the death, on January 8th, of **Dr. MARJORIE MAISIE SPEIRS**. She was the daughter of Mr. John Duggan of Builth Wells, and graduated B.Sc. of the University of Wales in 1924; after studying at the Welsh National School of Medicine she obtained the M.B., B.Ch. degrees in 1926. During the next five years Dr. Duggan held the post of demonstrator in the department of pathology of the Welsh National School of Medicine, and in 1931-2 joined the staff of the department of biochemistry in the University of Alberta Medical School, Edmonton. She returned from Canada in 1932 to become assistant bacteriologist to the Welsh National Memorial Association at Cardiff. She was a member of the Pathological Society of Great Britain and Ireland, and had joined the British Medical Association immediately after graduating in medicine. In June last Dr. Duggan married Mr. A. Speirs of Cardiff. Her untimely death is deplored by many colleagues and friends.

The following well-known foreign medical men have recently died: **Geh. Med.-Rat CHRISTIAN BÄUMLER**, emeritus professor of medicine at Freiburg, i.B., aged 97; **Professor GEORG SCHMIDT**, editor of the *Deutsche Zeitschrift für Chirurgie*; **Dr. FRANZ WEBER**, extraordinary professor of gynaecology at Munich, aged 56; **Professor ARTUR MEYER**, head of the surgical department of the Westend Hospital, Berlin, and author of a work on lung surgery, aged 48; **Dr. BURCI**, professor of clinical surgery at the University of Florence; **Dr. RAYMOND CESTAN**, professor of clinical medicine at Toulouse, aged 61; and **Dr. GASTON MELLO**, head of the Mexican department of health.

The dean of St. Mary's Hospital Medical School, Dr. C. M. Wilson, and Mrs. Wilson were entertained to dinner at Claridge's Restaurant on January 23rd, by members of the honorary medical and surgical staff of the hospital, and lecturers in the medical school, in celebration of the building of the new school and its opening by the King and Queen on December 12th, 1933. Sir William Wilcox presided, and on behalf of his colleagues presented Dr. Wilson with a beautiful silver cup, a copy of the famous "Fire of London Cup," and an illuminated address with the names of the subscribers. The following were also present:

Sir John Broadbent, Sir Ernest Graham-Little, Dr. Sidney Phillips, Mr. Leslie Paton, Dr. Harris, Mr. D. C. L. Fitz-William, Dr. T. E. Stevens, Dr. G. Harrison Orton, Dr. R. Miller, Professor Langmead, Professor Pannett, Mr. V. Z. Cope, Mr. F. Juler, Professor Frazer, Dr. J. Matthews, Dr. A. Fleming, Dr. J. Freeman, Dr. Gordon Bryan, Mr. R. M. Handfield-Jones, Mr. T. C. Hunt, Mr. A. W. Bourne, Mr. H. Smale, Dr. G. W. B. James, Dr. J. A. H. Brincker, Dr. W. D. Newcomb, Mr. Williamson-Noble, Dr. Courtney Gage, Mr. Leslie Williams, Dr. G. W. Ellis, Dr. W. Fish, Dr. G. R. Phillips, Dr. A. W. Matthew, Dr. L. Morris, Dr. Justina Wilson, Mr. V. H. Ellis, Mr. A. D. Wright, and Mr. B. E. Matthews.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Parliament reassembled on January 29th. In the House of Lords that day Lord Amulree introduced the Supply of Water in Bulk Bill. The House adjourned till February 7th. Lord Dawson of Penn put down for February 13th the second reading of the Contraceptives Bill. This proposes to make unlawful the sale or offer in any street or public place, or by means of an automatic machine which can be reached from a public place, any contraceptive. It also makes illegal, with certain exceptions, entry into any premises to offer such goods for sale and the display in or outside any shop so as to be visible to persons outside the shop, any contraceptives, any container, or picture or written description of such goods. The dispatch to unmarried persons under the age of 18 of circulars containing information relating to any contraceptive, for the purpose of trade or business, is also to be an offence. The text of the Bill is given in this week's *Supplement* at page 54.

The House of Commons was in committee for most of the week on the Unemployment Bill. Dr. Howitt gave notice that on February 1st he would ask the Minister of Health whether he would consider the present unrestricted sale of the barbituric drugs. Mr. Leckie put down a question for January 31st asking the President of the Board of Trade to repeal or reduce the duty on insulin. The Parliamentary Medical Committee has arranged to hear, at a meeting on February 7th, statements on the supplies and cost of insulin from manufacturing chemists. Professor Mellanby has also been asked to address this meeting. The Consultative Committee on Health and Housing arranged to discuss on January 31st the recent report on sterilization, Sir Francis Fremantle presiding. Sir Hilton Young was expected to attend this meeting.

Housing

On January 29th Mr. SHAKESPEARE informed Mr. Stourton that the slim clearance programmes received contemplated the demolition and replacement under the five-year plan of 224,515 houses containing over one million persons. There were in all 1,716 housing authorities, of which 1,604 had made returns, and 1,257 returns had been accepted. Mr. Shakespeare also told Mr. Hicks that during 1933 orders were confirmed under the 1930 Act providing for the demolition of 10,313 houses, while approvals were given for building 15,667 new houses under that Act.

On the same date Sir HILTON YOUNG informed Dr. O'Donovan that his housing officers were in consultation with the local authorities responsible for housing at Stepney. The borough council was clearing two areas containing 315 houses, and providing accommodation for 1,963 persons. The council was purchasing under the Act of 1930 an area containing seventy-two houses, and was about to commence rehousing work on this area. The L.C.C. was clearing two areas in the borough containing 682 houses, with assistance under the Act of 1923, and providing new accommodation for 4,306 persons. The purchase of further sites in Stepney for rehousing was under consideration.

Legislation to Reduce Road Accidents

On January 29th Mr. OLIVER STANLEY, replying to Mr. Anstruther-Gray and Mr. White, said that the Government was concerned at the returns of road accidents during 1933, and had decided to introduce legislation to deal with the subject at an early date. He desired to bring home to the public during the next few months the nature of the loss caused by road accidents and the extent to which they could be prevented by care and consideration for others on the part

of all users of the highway. He would in due course appeal to the Press, the B.B.C., and the film industry for their co-operation and assistance. He had made a contribution from the Road Fund towards the cost of a special campaign for the promotion of road safety, which the National Safety-First Association had projected for the spring and summer of the present year.

Notes in Brief

The Home Secretary regrets that he cannot promise legislation this session dealing with workmen's compensation.

Medical News

The winter conversazione for members of the University of London Medical Graduates' Society and medical graduates of the University of London not yet members of the society will be held in the Hastings Hall, B.M.A. House, Tavistock Square, W.C., on Thursday, February 15th, from 3.30 to 6 p.m. After tea a film, "Round the Empire on the Track of Malaria," will be described by Major Lockwood Stevens, and Mr. Ferris-Scott will conduct parties to see the setting-up of the *British Medical Journal* and other points of interest. Applications for tickets should be made not later than February 7th, to the secretary of the society, 9, Hardinge Road, N.W.10.

A discussion on the administration of the Housing Acts in relation to unfit individual houses will be opened by Dr. James Fenton, medical officer of health for Kensington, at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., on Thursday, February 15th, at 5.15 p.m., with Lord Balfour of Burleigh in the chair.

The chairman of the London County Council, Mr. Ernest M. Dence, LL.D., will open the newly altered and enlarged portions of the Council's Hackney Hospital in High Street, Homerton, on Wednesday, February 21st, at 2.45 p.m.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the fourth lecture-demonstration, by Dr. Clark-Kennedy, will take place on February 6th, at 2.30 p.m., at 11, Chandos Street, W., and will deal with vomiting and haematemesis; the fifth lecture, on February 13th, will be on constipation. The second of the series of lecture-demonstrations, on the second Saturday of every month throughout 1934, will be held at the National Temperance Hospital, Hampstead Road, on February 10th, at 3 p.m., when Mr. Acton Davis will lecture on orthopaedic cases. A week-end course in physical medicine has been arranged at the London Clinic and Institute of Physical Medicine on February 10th and 11th. The course will include treatment of gynaecological, neurological, and chest cases; manipulation; action of ultra-violet and infra-red rays. A whole-day course in diseases of the chest will be given at the Brompton Hospital from February 12th to 17th. Four ante-natal demonstrations will be given by Dame Louise McIlroy at the Royal Free Hospital, at 5 p.m. on Fridays, from February 16th to March 9th. Six demonstrations on the interpretation of pyclograms will be given by Dr. Cordiner, at 8 p.m. on Tuesdays and Fridays, from February 13th to March 2nd. Forthcoming courses include medicine, surgery, and the specialties, at the Prince of Wales's Hospital, February 19th to March 3rd; M.R.C.P. evening courses, Tuesdays and Thursdays, at the National Temperance Hospital, February 20th to March 6th; medicine, surgery, and gynaecology, at the Royal Waterloo Hospital, March 5th to 24th; proctology, at the Gordon Hospital, March 5th to 10th. Courses of instruction, lectures, clinics, etc., are open only to members and associates of the Fellowship.

A series of post-graduate lecture-demonstrations has been arranged at the Salford Royal Hospital, commencing on Friday, February 16th. Tea will be provided at 3.45 p.m. and the demonstrations will begin at 4.15. There is no fee for the course.

Miss Nina Symington, daughter of the late Professor Symington of Belfast, has bequeathed the residue of her estate, amounting to some £9,000, and to be known as the Johnson Symington Memorial Bequest, to the Anatomical Society of Great Britain and Ireland for Anatomical Research.

A post-graduate course will be held in Berlin during March and April under the auspices of the medical faculty of Berlin University and the German organization for post-graduate courses. From March 5th to 17th there will be lectures on internal medicine, and from March 19th to 25th on x rays. A surgical course, to include one day devoted to operative gynaecology, has been arranged for April 9th to 14th, and a course on hereditary biology for April 23rd to 28th. Further information concerning these courses may be obtained from the office of the International Post-Graduate Courses, Robert-Koch-Platz 7, Berlin, N.W.7.

The fourth congress of the International League against Rheumatism will be held in Moscow from May 3rd to 6th, 1934. Further information can be obtained from the office of the League, Keizersgracht 489, Amsterdam.

The next annual congress of the Royal Institute of Public Health will be held at Norwich from May 15th to 20th, 1934, on the invitation of the Lord Mayor and Corporation. The scientific work of the congress will be conducted in the following sections: State medicine and industrial hygiene; women and children and the public health; tuberculosis; veterinary medicine and agriculture; pathology and bacteriology.

The twentieth annual conference of the National Association for the Prevention of Tuberculosis will be held in the new Conference Hall of the London County Council on June 14th, 15th, and 16th. The conference will take the form of an all-round discussion concerning "The National Tuberculosis Scheme: The Experience of Twenty-one Years," and the subject will be introduced by Lord Astor, followed by leading representatives of central and local health authorities.

The Privy Council, in pursuance of the Pharmacy and Poisons Act, 1933, has nominated as additional members of the council of the Pharmaceutical Society Sir Humphry Rolleston, Sir Malcolm Delevingne, and Dr. James Andrew Gunn, professor of pharmacology, Oxford.

The Council of the Harveian Society has chosen the "Nutritional Factors in Disease" as the subject for the Buckton Browne Prize. The prize consists of a medal together with the sum of £100. The competition is open to any member of the medical profession registered in the British Isles or the Dominions, and is limited to candidates under 45 years of age. Essays must be sent in by November 1st, 1935. Further particulars may be obtained from Mr. Cecil P. G. Wakeley, D.Sc., F.R.C.S., 24, Queen Anne Street, W.1.

The following medical men were elected to the council of the Royal Microscopical Society at the annual meeting on January 17th: As vice-presidents: Professor D. M. Blair, Dr. G. M. Findlay. As an honorary secretary: Dr. R. T. Hewlett. As members of the council: Dr. A. S. Burgess, Dr. J. E. McCartney. Professor Frank Balfour Browne is the new president.

The Advisory Committee for Leverhulme Research Fellowships invites applications for the 1934 awards. These fellowships are intended in the first instance for the assistance of experienced workers rather than to add to the provision already existing for workers in the early stages of their careers. The trustees have in mind particularly men and women who are prevented either by pressure of routine duties or by any other cause from undertaking or completing an investigation of value. They have decided, as in 1933, that no definite limit shall be placed to the amount of individual grants, but that they will be adjusted according to the circumstances of each case. Fellows will usually be required to work at or in connexion with a recognized centre of research, either at home or abroad. No subject of inquiry is excluded from the scope of the scheme, but under present conditions the trustees intend that preferential consideration should be

given to subjects in which the existing provision is inadequate. The closing date for receipt of applications is March 1st, 1934. All applicants must be British born, and they must also be normally resident in the United Kingdom. Communications should be addressed to Dr. L. Haden Guest, secretary, Leverhulme Research Fellowships, Union House, St. Martin's le Grand, E.C.1, from whom forms of application may be obtained.

In the January issue of *Science Progress* Professor Major Greenwood contributes an article on epidemiology as a branch of experimental biology, which will be of great interest to all those concerned in this aspect of medicine.

The January issue of the American monthly journal *The Dental Cosmos* celebrates in appropriate fashion its seventy-fifth anniversary. In one among a number of historical articles the editor, Dr. L. Pierce Anthony, traces the influence of this periodical on dental literature. It was in 1859 that the *Dental News Letter*, founded in 1847, became merged in *The Dental Cosmos*.

Among the latest contributions to King Edward's Hospital Fund is £200, being the annual subscription of the President, H.R.H. The Prince of Wales.

The Second Spanish Congress of the Pathology of the Digestive System was recently held at Barcelona under the presidency of Dr. Gallant Mones, when the chief subject for discussion was the aetiology, diagnosis, and treatment of colitis.

Dr. F. W. M. Lamb, lecturer in pathology at the University of Birmingham, has been appointed professor of toxicology and medical jurisprudence to the medical faculty of the University of Cairo.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their names, and those who wish their names to be published in the *British Medical Journal*, should communicate with the Financial Secretary, British Medical Association House, Tavistock Square, W.C.1, and send a receipt of proofs. Authors overseas if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are: EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 6250 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Intrauterine Death of Foetus

"W. G." (Sussex) writes: I have had one or two cases of recurrent stillbirths due to foetal death in the last month of pregnancy, not associated with toxæmia, syphilis, or other disease of the mother, and apparently due to infarction of a substantial portion of the placenta. I should be grateful for any suggestions as to pathology and prophylaxis.

Silvester of Silvester's Method

Dr. M. BINGEN (Mathias Wynandsstraat 6, Maastricht, Holland) would be glad to know where he can obtain a portrait of Dr. Henry Robert Silvester, who published in 1858 his well-known method of resuscitating stillborn children and of restoring persons apparently drowned or dead.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Parliament reassembled on January 29th. In the House of Lords that day Lord Annulree introduced the Supply of Water in Bulk Bill. The House adjourned till February 7th. Lord Dawson of Penn put down for February 13th the second reading of the Contraceptives Bill. QUERIES AND ANSWERS

Intrauterine Death of Foetus

"W. G." (Sussex) writes: I have had one or two cases of recurrent stillbirths due to foetal death in the last month of pregnancy, not associated with toxæmia, syphilis, or other disease of the mother, and apparently due to infarction of a substantial portion of the placenta. I should be grateful for any suggestions as to pathology and prophylaxis.

Silvester of Silvester's Method

Dr. M. BINGEN (Mathias Wynandsstraas 6, Maastricht, Holland) would be glad to know where he can obtain a portrait of Dr. Henry Robert Silvester, who published in 1858 his well-known method of resuscitating stillborn children and of restoring persons apparently drowned or dead.

Threadworms

Dr. FRANCIS JOHNSTON (Oxton, Birkenhead) writes: I have found garlic oil very useful in ridding adults of threadworms. The oil is put up in capsules by Allen and Hauburys. I believe that it is not wholly for the sake of the flavouring that garlic is so popular in Continental kitchens. In the salad it may be an effective anthelmintic.

Dr. E. C. MURIE (Glasgow) writes in reply to the query by "Glevum" (January 27th, p. 178): There is no intestinal parasite that will persist on a diet in which raw garlic is incorporated. As with all other methods of treating worms, meat and other purine-containing foods should be strictly limited, and an abundance of raw fruit and conservatively cooked vegetables should be taken with plain wholemeal bread, and plenty of plain water between meals. The garlic should be chopped up finely, about two or three "cloves" or divisions, so that they could be swallowed without chewing. This should be done at the two largest meals of the day. No purgatives are necessary unless the patient be habitually constipated, when a large dose of salts in a pint of warm water, fasting, should be taken each morning. In the case of threadworms I generally help matters by giving a quart enema (for an adult) in which are dissolved two drachms of common salt and half an ounce of turpentine: retain ten minutes. By the use of garlic I cured a woman of *Ascaris lumbricoides* in thirty-six hours, during which time she passed a male worm 13½ inches long and a female with a bunch of newly hatched young, which were uncountable. I might add that garlic has many other therapeutic uses besides that of a vermifuge. It is a pity the intolerable odour renders it impracticable for common use as an article of dietary in this country.

"X" (Kew) writes: I have personally found the treatment for threadworms given in the *Journal* of August 22nd, 1931 (p. 336), to be the only efficacious one.

* The treatment referred to is described in the course of an article by Colonel W. P. Macarthur, entitled "Pruritus Ani." Briefly, it consists of (1) four-ounce rectal injections of saline solution (two ounces of salt to a pint), and (2) the use of two grains of santonin and half an ounce of calomel by mouth. Full details are given in the article.

Income Tax

Subletting of Portion of House Unfurnished

"C.'s" house is assessed to income tax, Schedule A, on a net value of £90; he sublets a portion, for which he receives a rent of £100. Does the Schedule A assessment cover his full liability to tax?

* Schedule A deals with income from property, and if the £100 is derived only from the consideration that a right of occupancy of a part of the property is given, then no part of the rent can be assessed except as part of the Schedule A assessment on the property as a whole. This principle was made clear in a *fairly recent case*, usually quoted as the Salisbury House case. *Prima facie*, therefore, the assessment of £90 in "C.'s" case covers his full liability. If, however, other considerations enter into the question—for example, that "C." provides some services in connexion with the letting, or that the £100 includes some annual sum in the nature of a payment for goodwill, there may be further liability, either direct on "C." under Schedule D, or indirectly through deduction of tax by "C.'s" tenant.

LETTERS, NOTES, ETC.

Herpes and Varicella

Dr. J. F. P. FORSTER (Porlock) writes: The correspondence in the *British Medical Journal* on the above subject, and especially Dr. A. H. Spieker's letter (December 30th, 1933), prompts me to record an almost similar case in my practice last November. A man, aged 47, came to me with a very severe attack of herpes over the spine of the right scapula, inner aspect of arm and forearm, and front of chest. He said he first noticed it two days previously. Exactly eleven days afterwards I was called to see his daughter (aged 10), who was rapidly developing a typical attack of varicella. The father had definitely had varicella in childhood.

Prescription of Hypnotic Drugs: A Suggestion

"PHARMACIST" writes from Cornwall: In view of the widespread publicity given to recent controversies over hypnotic drugs, may I offer a simple suggestion to those medical men who find these drugs of use in practice. Frequently a small quantity of drug (say, "Dial, tablets 20") is ordered on a prescription. Unfortunately the prescription can be taken again and again to a chemist, and an unlimited supply of the tablets obtained. The chemist has the right in law to do this, providing, of course, that a record is kept of each transaction. Thus the patient goes on taking these drugs long after medical supervision has stopped, and usually takes far too much. It must be admitted that there is distinct danger in this state of affairs. The remedy is this. The doctor should write at the bottom of each prescription, "Not to be repeated," or "Kindly retain script." Either of these injunctions will be regarded by the chemist, unless he is entirely devoid of professional responsibility (I hope all good practitioners avoid such). I think it will be found that very few chemists will supply hypnotics without taking medical advice, even though they have a perfect right to do so under the Poisons and Pharmacy Acts (Part 1).

Prevention of Colds in Schools

Dr. R. W. P. HALL (Windermere) writes: At the beginning of last term I had a talk with the head master of a boy's preparatory school which I attended, with regard to making a serious effort to keep the school clear of colds and influenza. We decided to exploit the antiseptic properties of the onion, and arrangements were made to give the boys one dessertspoonful of onion syrup night and morning throughout the term. The results speak for themselves. There were no cases of colds, coughs, or influenza among the whole-time boarders who were given the syrup regularly. On two occasions week-end boarders came back on the Monday with streaming colds, which went no further among the boys, but attacked two members of the teaching staff, who had not taken the syrup. On another occasion a visitor to the school saw two or three of the boys in a small room two hours previous to going to bed with influenza.

The Professional Classes Aid Council

The Professional Classes Aid Council exists to relieve distress among the professional and other highly educated classes. Founded in the emergency times of October, 1914, its work did not end with the war, and it continues to exercise its kindly functions of relieving immediate emergencies and enabling its beneficiaries to bridge over temporary difficulties while in the search for permanent employment. In its last annual report, which covers the twelve months ending April 30th, 1933, it is stated that expenditure on relief has increased by over £2,000, while the contributions have diminished by £600. Among those who received assistance were medical practitioners, dentists, veterinary surgeons, and officers of the Services and the Mercantile Marine. Details are given in the report of various cases relieved. Many students, including some for the medical profession, are being assisted to proceed with their studies. In some cases the grants take the form of a loan which is repayable. The British Medical Association is represented on the council by its Treasurer, Mr. N. Bishop Harcourt, F.R.C.S., and Lord Dawson of Penn is one of the patrons.

Book-keeping for the G.P.

In these columns on December 9th last we published a letter from Dr. W. H. Rowthorn of Sheffield on the subject of book-keeping for the general practitioner, in which he drew attention to his own simple method, the details of which were published in the *Journal* many years ago. We have now received from Dr. Rowthorn a small brochure setting forth the method he has devised. The general scheme is substantially the same as the earlier one, its success in application resting chiefly on the use of "slips," which take the place of day-book, prescription book, and waiting list. The only other "books" required are an ordinary double-entry ledger and a cash-book. The brochure may be obtained direct from Dr. Rowthorn, 52, Brocco Bank, Sheffield, 11, price 5s.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 47, 48, 49, 52, and 53 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 55.

SPONTANEOUS HYPOGLYCAEMIA ASSOCIATED WITH HEPATITIS

BY

HENRY MOORE, M.D., D.Sc., F.R.C.P.I.

PROFESSOR OF MEDICINE, UNIVERSITY COLLEGE, AND PHYSICIAN TO THE MATER MISERICORDIAE HOSPITAL, DUBLIN

W. R. O'FARRELL, L.R.C.P. & S.I.

PATHOLOGIST TO THE MATER MISERICORDIAE HOSPITAL, DUBLIN

AND

M. F. HEADON, B.Sc.

(With Special Plate)*

In 1931 Moore, O'Farrell, Malley, and Moriarty¹ described a case of acute spontaneous hypoglycaemia associated with amylose dyspepsia, and reviewed the clinical literature up to date. The acute hypoglycaemia in that case was apparently superimposed upon a mild chronic hypoglycaemia, and the former condition seemed to be in some degree related to the amylose dyspepsia. This appears to be the only case recorded in the literature in which amylose dyspepsia and acute hypoglycaemia coexisted, and the subsequent history of the patient is described at page 227. At the time of that communication about twenty-four cases of acute spontaneous hypoglycaemia had been reported. Since then several others have been added, and Wauchop² has recently published an excellent critical review of the literature of the whole subject of hypoglycaemia.

PATHOGENY OF HYPOGLYCAEMIA

The regulation of the blood sugar level is believed to be largely due to the interplay of those internal secretions which regulate carbohydrate metabolism.

(1) *Insulin*, the most important of them, lowers blood sugar, but the mechanism of its action is not fully understood. There is evidence that hyperglycaemia itself directly stimulates the islands of Langerhans to produce insulin. Clinically, conditions which increase the amount of insulin in the circulating blood, whether by injection or by over-production from the islands of Langerhans, are important causes of hypoglycaemia. (2) *Adrenaline* causes a rise in the blood sugar level. It is said to act by releasing stored liver glycogen and converting it into glucose; possibly also it causes a transference of glycogen by way of lactic acid from the muscles to the liver. Its injection is often used therapeutically in hypoglycaemia, but has relatively little effect on the blood sugar level when the hepatic glycogen stores are exhausted—for example, in starvation. The interaction of insulin and adrenaline, in this respect, is believed to be controlled by a nervous centre in the pons, and it has been suggested recently that an increase in the blood sugar stimulates this centre and so causes an increased production of insulin from the islands of Langerhans through the vagus nerve. Conversely, it has been stated that hypoglycaemia possibly causes an increased output of adrenaline through the sympathetic system. (3) *Pituitary* inhibits the action of insulin, but it also opposes the glycogenolytic action of adrenaline. It, too, is used as a therapeutic agent in insulin hypoglycaemia. The pituitary gland plays too complicated a part in the regulation of blood sugar to be further discussed here. Certain cases of pituitary tumours may be associated with hypoglycaemia and others with hyperglycaemia. (4) *Hyperthyroidism* is sometimes associated with a tendency towards hyperglycaemia, and myxoedema with hypoglycaemia. (5) *Hormones of other ductless glands* have been said to have effects on the blood sugar level, but, clinically, these effects are probably not commonly very important.

The liver is the main reservoir of glycogen from which sugar can be mobilized in the blood stream, and lack of the hepatic glycogen stores may be a factor in the production of hypoglycaemia.

The relation between glycogen, blood sugar concentration, and insulin is apparently a complicated one. Cori³ states that under post-absorptive conditions the organism depends

mainly on the liver glycogen for its supply of blood sugar, the muscle glycogen being apparently unable to contribute sugar to the blood directly; the final step in the process of sugar formation in the liver is hydrolysis of glycogen, and insulin and adrenaline are the most important factors influencing this transformation. That author points out that when insulin is lacking, hydrolysis of liver glycogen remains unchecked, this leading to disappearance of liver glycogen. The decrease in liver glycogen seen under certain conditions after insulin injection is believed to be mainly due to hypoglycaemia, which is a powerful stimulus to glycogenolysis; the fall in liver glycogen in this case is not directly caused by insulin, but is a secondary phenomenon due to hypoglycaemia. Again, it is said³ that insulin facilitates the accumulation of liver glycogen in the normal animal, but how it does so is not clear. It appears to be settled that the level of blood sugar concentration is a factor influencing the rate of liver glycogen formation.

Mann and Magath⁴ showed that extirpation of the liver in dogs caused profound hypoglycaemia. There is considerable evidence in the literature that injury to the hepatic parenchyma may cause hypoglycaemia, presumably by interfering with the hepatic glycogenic function. Feigl and Luce,⁵ in 1918, demonstrated hypoglycaemia in four cases of acute yellow atrophy of the liver. Rabinowitch⁷ recorded a case of acute yellow atrophy of the liver, in which the hepatic parenchyma was almost completely destroyed, and in which there was marked hypoglycaemia (16 mg. per 100 c.cm.), no urea in the blood, and acute degenerative nephritis with fatty degeneration of the renal tubules. Bodansky,⁸ in 1923, brought forward evidence to show that hypoglycaemia occurs in dogs as a result of severe liver damage by chloroform, by phosphorus, and by hydrazine poisoning. Crawford⁹ described a case of marked hypoglycaemia apparently due to considerable destruction of the liver parenchyma by primary hepatic carcinoma, and Nadler and Wolfer¹⁰ recorded a similar case about two years earlier. McIntosh¹¹ reported a case of acute phosphorus poisoning in a boy of 16 months of age, with enlargement of the liver and hypoglycaemia; the patient recovered. Joseph¹² described two cases of hypoglycaemia in each of which the liver at necropsy was proved to be the seat of extensive fatty change. Canmidge¹³ suggested that many cases of recurrent attacks of vomiting, pernicious vomiting of pregnancy, and cyclical vomiting of children are attributable to hypoglycaemia due to hepatic dysfunction. Cross and Blackford¹⁴ reported a case of fatal hepatogenic hypoglycaemia following neocarsphenamine injection.

It seems reasonable, therefore, to suppose that profound disease of the liver, by interfering with its glycogenic function, might cause hypoglycaemia. The case reported in this paper would seem to be capable of explanation on the basis of a degree of degeneration of the liver cells sufficient to interfere with the hepatic glycogenic function.

Wauchop summarizes the possible causes of hypoglycaemia as follows:

1. *Excess of Insulin*.—Therapeutic injections, tumours or hyperplasia of the islands of Langerhans, or functional hyperinsulinism (idiopathic or spontaneous hypoglycaemia).
2. *Lack of Opposing Secretions*.—Diseases of the suprarenal glands, pituitary tumours, or myxoedema.
3. *Lack of Glycogen*.—Destruction of reservoirs (diseases of the liver, wasting of muscles), abnormal excretion of sugar (renal glycosuria, lactation), active depletion of stores (muscular exercise), or failure to replenish stores (starvation).

4. *Interference with Regulating Centre.*—Nervous diseases affecting the pons, or overaction of the vagus.

In the case of the last (4), the clinical literature is too scanty for any definite conclusions to be arrived at; and Wauchope thinks that it is doubtful whether starvation alone can so lower the blood sugar as to cause symptoms of hypoglycaemia in perfectly normal persons.

CASE RECORD

The case now to be described was that of a married woman, poorly nourished, aged 40 years, who was admitted to the Mater Misericordiae Hospital on May 30th, 1933, about 6 p.m., in coma. She was referred to one of us by Dr. W. Hooper.

The pulse rate was 80 and the respirations 22 per minute; the temperature (axillary) was subnormal. The patient looked somewhat anaemic as she lay unconscious on the bed. She muttered occasionally and indistinctly, shrieked loudly now and then, and performed aimless movements with the arms. The blood pressure was 98/70, the knee-jerks were absent, and Babinski's sign was bilaterally negative, but the limbs were slightly spastic. The clinical physical examination was otherwise normal, and the urine (catheter specimen), which was normal in colour, contained no albumin, casts, sugar, or abnormal formed elements. The pupils reacted to light, although sluggishly, the eye grounds were normal, and the examination of the lungs revealed no evidence of disease. Unfortunately, neither a blood count nor a Wassermann test was done, but there was no special reason to suspect syphilis. The blood sugar registered only 25 mg. per 100 c.cm. (Folin-Wu technique). Glucose drinks and glucose enemata given during the night were not retained.

The following morning the patient was still comatose, but quiet; the temperature was 99.2° F., and at 8.30 a.m. the blood sugar was 29, and the blood urea 42 mg. per 100 c.cm. She retained some glucose by mouth during the morning, and at 1.59 p.m. her blood sugar was 31 mg. per 100 c.cm. At 2 p.m. an intravenous injection of 25 grams of glucose into the right median basilic vein was started; the injection took about ten minutes, and on its completion the patient had become sufficiently conscious to write her name, but mentally she was still rather sluggish in answers to questions, was a little indistinct in speech, and, although the eye movements appeared normal, she complained that she "saw crooked"; when a finger was held vertically before her eyes she said it was held obliquely. Just after the injection the blood sugar (left median basilic vein) was 238 mg. per 100 c.cm., she was able to sit up in bed and to retain glucose drinks, and examination then revealed no paralysis of the limbs or evidence of intracranial tumour. A little over two hours after the intravenous glucose injection the blood sugar had fallen to 94 mg., and two hours later it was 104 mg. per 100 c.cm. About 5.30 p.m. the patient became very listless and inattentive, and about 6 p.m. (blood sugar 104 mg.) again became comatose. An electrocardiogram taken at 7 p.m. was normal, and a little later vomiting started and no glucose was from then on retained by mouth or rectum. Coma gradually became deeper, and adrenaline injections were tried, but the patient died at 3 o'clock on the morning of June 1st.

The previous history was obtained from the husband after the death of the patient. The family history revealed nothing of relevant importance. Six healthy children are alive, and there were no miscarriages, abortions, or stillbirths. Slight chloroform anaesthesia was used at one birth in 1924, but at no other. There was no alcoholic history. The patient was quite well up to three years before admission (about one year after the second last delivery), when she became listless, and began to take less and less interest in life. During the last year appetite had gradually failed, attacks of vomiting had occurred, and these were often rather persistent, so that she lost some weight; she became more listless, and on two occasions, about a year before admission, she became dazed or semi-conscious for almost an hour, not recognizing her surroundings or relatives and having no memory of these attacks afterwards. On March 26th, 1933, she was delivered of healthy twins (which she never nursed), but the birth was followed by severe post-partum haemorrhage. She recovered from the latter, but vomiting was troublesome up to admis-

sion, and listlessness became progressively greater until she lost consciousness on the day of admission to hospital. She never had diabetes or received insulin, and she had never had jaundice.

Post-mortem Examination

Only a partial post-mortem examination was permitted nine hours after death, and this was limited to such organs as were accessible by opening the abdomen. The skull was x-rayed post mortem by Dr. J. A. Geraghty, and the picture of the sella turcica was normal. The gastro-intestinal tract showed no striking naked-eye or microscopical pathological changes. The liver was about normal size, its surface showed some pale and pink mottling, and on section its substance was reddish, soft, and almost diffident. The spleen was slightly enlarged, its surface was congested, and it was almost diffident. The pancreas, kidneys, and suprarenals appeared normal. The pancreas was cut up into small pieces in a careful search for tumours, but none were found.

A summary of the histological report on sections is given:

Liver: The characteristic lobulated appearance of the liver is almost lost, and the pattern is more cellular than normal. The existent individual liver cells are prominent, and in general are markedly separated from one another, but many cells have been destroyed, or are markedly degenerated with loss of nuclei; the destruction is of single cells or small groups of cells throughout the whole organ; a striking feature is, however, the prominence and variation in the size of the nuclei, a considerable number of which are large and hyperchromatic; a few liver cells show mitotic figures, and many contain two nuclei. These cellular changes are not limited to any special portion of the liver, nor to any special area of the liver lobule. The picture, therefore, is one of parenchymatous destructive and regenerative changes occurring side by side, the former being the more prominent. There is no fatty degeneration or infiltration, neither are there any haemorrhages, inflammatory reaction, or replacement fibrosis. The bile ducts are normal. Hepatic glycogen was not determined. Its estimation so long after death would probably give information of little value.*

Spleen: The spleen is congested, but does not show any marked cellular change.

Kidneys: The kidneys show some slight necrosis and desquamation of the epithelium of the convoluted tubules, but the glomeruli are normal.

Pancreas: The pancreas does not show any pathological change, and the islet tissue is normal.

Suprarenals: The suprarenals are normal.

Photomicrographs illustrating the liver changes are shown in Figs. 1 to 4 on Plate.

Conclusions

The main pathological changes in the organs examined are present in the liver, and are in the nature of a subacute parenchymatous hepatitis. Considerable reparative change is taking place in the liver parenchyma, as evidenced by the variation in the size of the cells and by hyperchromatism of many and mitosis of some of the liver cell nuclei.

Discussion

In considering the available data of this case the work of Mann and Magath* appears to be of fundamental importance. These authors showed that complete removal of the liver in dogs caused, within a few hours, muscular weakness, loss of reflexes, and flaccidity; later there was exaggeration of the reflexes, muscular twitchings, and convulsions, often with terminal vomiting and subnormal temperature, and death in coma in about twenty-four hours. Total removal of the liver was quickly followed by progressive decrease in the blood sugar level, until at death it was usually not in excess of 30 mg. per 100 c.cm. The development of the characteristic symptoms exactly paralleled the decrease in the blood sugar level. At least 85 per cent. of the liver had to be extirpated to produce hypoglycaemia. They suggested that a plausible explana-

*Owing to the unusual characters of this case we submitted a section of the liver to Dr. J. W. McNee of London for his opinion, giving him the relevant clinical details. Dr. McNee very kindly permits us to state that his view of the pathological process in the liver, arrived at independently, coincides with ours as stated above. We desire to thank Dr. McNee, who is a well-known authority in this field, for his courtesy.

tion of the decrease in blood sugar was that hepatectomy either removed the control of the blood sugar supply or interfered with sugar utilization by depleting the carbohydrate store or a substance concerned in carbohydrate utilization. Further, Mann and Magath⁵ later showed that hepatectomized hypoglycaemic dogs, showing the above symptoms, could be immediately restored to a seemingly normal condition by the intravenous injection of 0.5 gram glucose per kilogram of body weight. Immediately after the glucose injection the blood sugar reached a high level, and then gradually fell. By repeated intravenous injections of glucose the animals could be kept alive and without the characteristic symptoms (which were apparently almost entirely due to hypoglycaemia) for about twenty-four hours, but then, notwithstanding a normal blood sugar level still being maintained, the animals suddenly became comatose and died quietly. The hypoglycaemic symptoms were thus different from the final picture, which was probably "dependent on some change in metabolism other than carbohydrate."

It is tempting to suggest that the case now reported is almost the clinical equivalent of the physiological experiments of Mann and Magath, that hypoglycaemia due to liver cell destruction from disease largely coloured the clinical picture, and that death was due to hepatic failure. It is interesting, also, in this connexion to note that signs of marked listlessness and slowing of mentality, with some flaccidity of muscles, began to reappear soon after the intravenous glucose injection, and that coma reappeared when the blood sugar was 104 mg. per 100 c.cm., four hours after the intravenous injection.

INTERPRETATION

As we were not permitted to perform a complete post-mortem examination, the exact aetiology of the condition is necessarily somewhat doubtful. However, taking into account the possible pathogeny, we suggest that, although a remotely possible cause was functional hyperinsulinism, the most probable one was disease of the liver interfering with its glycogenic function. Certainly no tumour of the islands was discovered in the pancreas, and if there was an excessive secretion by the cells of the islands of Langerhans, it must have been purely "functional." On the other hand, a definite alteration of the liver structure was found, and although this was an unusual condition, it is interpreted as being a subacute parenchymatous hepatitis. Although no determination was made of the liver glycogen content (it is doubtful whether this would yield information of great importance nine hours after death), it is quite probable that this structural change in the liver was consistent with an alteration of its function in carbohydrate metabolism. Consequently, we are inclined to the view that the cause of the hypoglycaemia in this case was parenchymatous hepatic degeneration; whether the latter condition has any relation to so-called acute yellow atrophy of the liver, and whether it had any connexion with pregnancy, we cannot say; from the information at our disposal its aetiology is obscure.

M.B., B.Sc.

ASSISTANT PHYSICIAN

HOUSE-PHYSICIAN

MATER MISERICORDIAE HOSPITAL

This case was fully described in the *British Medical Journal* in 1931. The patient, a woman aged 27 years, was admitted to the Mater Misericordiae Hospital in May, 1930, in hypoglycaemic coma, the blood sugar being 35 mg. per 100 c.cm.; her limbs were rigid and the Babinski sign was bilaterally positive. She promptly recovered consciousness on the intravenous injection of 10 grams of glucose, the rigidity passed off, the Babinski sign became negative, the blood sugar rose to 111, and the coma never recurred during fourteen months of observation. The acute hypoglycaemia was associated with amylaceous dyspepsia, which was successfully treated; but, although acute hypoglycaemia did not reappear, there remained a mild continuous chronic hypoglycaemia (62 to 78 mg. sugar per 100 c.cm. of blood), upon which the acute hypoglycaemia causing coma was apparently superadded.

On November 19th, 1933, the patient was again admitted to the hospital in an unconscious condition; the clinical picture was, however, different from that seen on the first admission: there was no rigidity of the limbs; on the contrary, the muscles were flaccid; the tendon reflexes and Babinski's sign were negative; there was some resistance to forcing the eyelids apart, the conjunctival reflex was present, and the pupils reacted to light; loud bubbling rales were heard all over the chest, so that the heart sounds could scarcely be distinguished. No pulse could be felt at the wrists, but the right superficial temporal artery pulse rate was 84, and the blood pressure could not be determined over the brachial artery. There was no cough or sputum, and the clinical picture suggested post-influenzal pneumonia. The axillary temperature was 100° F. and the respirations were 44 per minute. The blood sugar, a couple of hours after admission, was 66 and the blood urea 84 mg. per 100 c.cm. The urine was normal. Twenty-five grams of glucose were given intravenously, after which the blood sugar rose to 217 mg. per 100 c.cm. Glucose was given by stomach tube and per rectum, but was not retained, and the patient died about twelve hours after her admission to hospital.

Inquiry from her husband revealed that she had felt quite well on the morning of admission and arose after breakfast. Feeling cold about 11 a.m., she went to bed again. She refused her dinner at 2.30 p.m., and vomited a little whisky taken about 5 p.m. At 6 p.m. she became unconscious, and at 8 p.m. was seen by Dr. L. Masterson, who noted the rales in the chest and referred her to one of us as he knew we were interested in the case. She had become comatose, without convulsions, about nine months previously for about two hours, but recovered without treatment. During the past two years she occasionally complained of staggering or giddiness, and

blurring of vision when reading; apart from constipation and frequent listlessness we could learn nothing further of significance.

POST-MORTEM EXAMINATION

Fortunately we were able to obtain, about two hours after death, a complete necropsy, of which the following is a relevant summary:

The body was well nourished, the pubic and axillary hair was scanty and short, the hair of the head was fine and rather sparse at the vertex. All the organs were carefully examined by the naked eye and microscopically, unless otherwise stated.

Abdomen.—The spleen weighed 180 grams; its substance was dark red and firm, and on microscopical examination there was venous engorgement. The kidneys were normal, except for venous congestion and slight fibrosis of the interstitial tissue. The suprarenals were normal macroscopically and microscopically. The pancreas was normal. It was carefully sectioned in a search for adenomata of the island tissue, but none were found; the cells of the island tissue appeared normal, and the islands did not seem to be increased in number or size. Sections from various parts of the pancreas showed a slight general fibrosis. The liver weighed 1,300 grams, its surface was smooth and pale; on incision it showed a slightly "marbled" appearance. Microscopical examination showed a general venous congestion, with some slight round-celled infiltration about the smaller bile ducts; there was slight fatty change, which was in the nature of an infiltration confined to a small zone about the intralobular veins; slices were fixed in alcohol, but no glycogen could be demonstrated. The stomach and intestines were normal on naked-eye and microscopical examination, and the gall-bladder, urinary bladder, and uterus and its adnexae were normal on naked-eye examination.

Heart and Lungs.—The pericardium contained about 110 c.cm. of pale fluid, the heart, which weighed 240 grams, was macroscopically normal, except for slight thickening of the mitral valve cusps and some flaccidity of the right ventricle. Both lungs showed bronchopneumonia. There were petechial haemorrhages under the visceral pleura. The substance of the lung felt "shotty," and incision showed numerous scattered, plum-coloured, consolidated patches of various sizes. A large consolidated area about the size of a tangerine orange was present in the central part of the upper lobe of the left lung. Pus exuded from the smaller bronchi in the consolidated areas. Microscopical examination showed bronchopneumonia, and Gram-Weigert stain showed pneumococci to be present.

Other Organs.—The thyroid was small, and weighed only 8 grams. Stained sections showed normal structure and no lack of colloid substance; there was slight flattening of the cells lining the alveoli, and there was no fibrosis. The brain and brain stem were normal on naked-eye section, but the brain surface was slightly congested and oedematous.

The pituitary gland was normal on naked-eye and microscopical examination. The thymus was absent.

BIOCHEMICAL INVESTIGATION OF LIVER

As it seemed important to learn, if possible, something about the carbohydrate and glycogen content of the liver, Professor E. J. Conway kindly undertook to investigate this question, and his report is as follows:

Considering that two hours had elapsed from the death of the subject to the time of excision of the liver, it was decided to estimate the total carbohydrate, and so obtain at least a maximum value for the ante-mortem glycogen content. It is well known, since the classical experiments of Claude Bernard, that a marked breakdown of glycogen into glucose takes place in the liver after death, and that in two to three hours the greater part of the pre-formed glycogen may have disappeared. The estimate of the total carbohydrate under such conditions, with subsequent calculation of the glycogen, supposes that none of the formed glucose disappears by glycolysis. That no appreciable glycolysis takes

place is shown by the early experiments of F. Rohmann, described in his *Lehrbuch der Biochemie* (Berlin, 1908), in which no marked diminution of the total carbohydrate had occurred in one and a half to two hours after death. The estimate of the total carbohydrate, according to the same worker, using acid hydrolysis, gives figures always in excess of that reckoned from the original glycogen and glucose content. The present results will state, therefore, only a maximum possible value for the original glycogen content of the sample provided, and are almost certainly higher than the true figure.

In the method used 10 grams of liver, cut into sections, were boiled in 50 c.cm. of distilled water for twenty minutes. From the stoppered flask—after remaining overnight—the liver substance was removed and carefully ground to a paste with the finest Merck's quartz sand, continued extractions with water being taken, and finally the whole made up to 100 c.cm. with water. The mixture was shaken for some time and filtered; 5 c.cm. portions of the filtrate were taken and, equal quantities of N/1 acid having been added, the mixtures were boiled for ten to thirty minutes. These were subsequently neutralized and made up to 100 c.cm. with water. The glucose content was then examined by the Hagedorn-Jensen method, using the precipitation stage of this method as well—it being necessary, however, to take upwards of 4 c.cm. of the fluid for analysis.

The results were certified by several repeats, controls, and blanks, and may be summarized as follows:

- (1) Glucose in liver sample examined, 0.9 per cent.
- (2) Total carbohydrate in liver sample examined (as glucose), 1.01 per cent.
- (3) Maximum value of glycogen in liver examined, 0.12 per cent.
- (4) Maximum value of glycogen in ante-mortem liver, 0.94 per cent.

In the calculation of the third and fourth items it is reckoned that 1 gram of glycogen gives 1.07 grams of glucose. The values given by Hammenstein for the glycogen content of the liver in the normal animal are from 1.2 to 4 per cent. Figures of 18 and even 20 per cent. have been obtained in experimental animals. The values given by Rohmann for upwards of twenty experimental animals receiving dietaries with normal food constituents (these being varied in different ways) show 1.69 as the lowest for a dog fed on meat alone. For two dogs fed on sugar and biscuits he obtained the surprising figures of 19.5 and 19.3 per cent. glycogen. The figures of Rohmann show that post-mortem glycolysis in the liver is practically negligible for two hours after death, although glycogenolysis is marked. Therefore one may conclude that the figures obtained suggest that the liver before death was poor in glycogen.

DISCUSSION

The interpretation of the case from the history and post-mortem findings is by no means clear. Apparently the acute hypoglycaemic coma was in some degree related to amyloaceous dyspepsia occurring in conjunction with chronic hypoglycaemia, but the cause of the latter condition is still obscure. Possibly, in view of the small size of the thyroid gland, a mild degree of hypothyroidism might be held responsible, but, on the other hand, the thyroid, though small, did not, on microscopical examination, show any great departure from the normal, and there was no gross clinical sign of hypothyroidism. It is unfortunate in this connexion that the patient on her first admission refused to allow her basal metabolic rate to be estimated. However, it is difficult to believe that whatever degree of hypothyroidism the patient may have had would be great enough to keep the blood sugar down to the levels existing after the cure of the amyloaceous dyspepsia. Again, liver disease could hardly be held definitely responsible for the chronic hypoglycaemia, because the pathological changes in the liver were too slight—the hepatic venous congestion must have been terminal. As regards the liver glycogenic function, the maximum possible ante-mortem

glycogen value for this liver was below what one might expect as normal, but normal control figures for the human do not seem to be readily available. All that can be said is that apparently this liver was poor in glycogen. But in the absence of further evidence, and remembering that the patient took or retained little food for twenty-four hours (apart from the intravenous glucose given about eleven hours before death), it would be rash on this score to attribute the chronic hypoglycaemia to a hepatic cause. To account for the chronic hypoglycaemia one is apparently driven, in the present state of knowledge of this complicated subject, for want of a better explanation, to consider absolute hyperinsulinism; but here again there is very little evidence to go upon. Finally, it is interesting to speculate as to whether the fulminant

course of the bronchopneumonia may have been determined to some degree by the chronic hypoglycaemia.

NOTE.—Since the above was written we have come across a case of apparently true hyperinsulinism, or what certain authors might call dysinsulinism. This was a man, aged 28 years, who complained of slight mental confusion, slight dimness of vision, and weakness about three hours after the heavier meals. The fasting blood sugar was only 80 mg. per 100 c.cm. After ingesting 50 grams of glucose the blood sugar in half an hour was 90, in one hour 135, in two hours 97, in three hours 64, in four hours 66, and in five hours 78 mg. per 100 c.cm. His physical examination was normal in all respects, and we could find no evidence to implicate either the ductless glands or the liver.

A CASE OF OVARIAN PREGNANCY*

BY

W. C. SPACKMAN, M.B., B.S.LOND., F.R.C.S.ED.
LIEUTENANT-COLONEL I.M.S.

PROFESSOR OF MIDWIFERY AND GYNAECOLOGY, GRANT MEDICAL
COLLEGE, BOMBAY

(With Special Plate)

The following case of ovarian pregnancy appears worthy of record in view, first, of the great rarity of the condition, and, secondly, of the circumstances leading up to it.

Mrs. C., aged 38, a European, formerly a maternity nurse, consulted me privately on April 26th, 1933, for sterility.

Although married for only twenty months, in view of her age and the fact that her menstruation was becoming scanty she was anxious to become pregnant as soon as possible.

Menstruation.—Every twenty-six days, duration five days; latterly duration three and two days. Last menstrual period April 20th to 22nd.

Physical Examination.—Perfectly healthy type. Pelvic organs normal.

Advised a Rubin inflation of the Fallopian tubes about ten days after first day of each period for three or four months, and to take agomensin for a week before each period.

Treatment.—A Rubin inflation of the Fallopian tubes was carried out on May 1st; pressure 120, both tubes patent. The patient had sexual connexion two or three times in the following few days as advised, but it was later ascertained that she had also had connexion three days before the test was performed.

The patient took agomensin (two tablets three times a day) from May 11th, and was seized with severe lower abdominal pain on the 14th. The pain was so severe that she was admitted to a nursing home. I was out of Bombay, and so am unable to particularize further about this attack. She was given hyoscine. The pain subsided, and she left the home in two days.

She herself attributes the pain to the agomensin. The period expected at the middle of May did not appear. She came to see me again on May 31st. She then had a slight uterine haemorrhage, like a mild menstruation, but no pain. She stated that, since the pain of May 14th, she could not lie comfortably on her left side.

She was not examined, in view of the probability of the missed period indicating pregnancy and the slight haemorrhage a threatened abortion, but she was ordered rest and sedatives, and told to return again in a few days and to keep in touch with me meanwhile.

* This case was reported at a meeting of the Bombay Branch, held in the Grant Medical College, Bombay.

She returned on June 14th and reported that she had "miscarried" on June 8th. From her description of what she passed, and her experience as a nurse, I at first considered that this was probable, but on examining her I found the uterus anteflexed, normal in size, and a lump, situated behind and to the left of it, slightly tender, about the size of a plum, and firm in consistency. There was pulsation between this lump and the left side of the uterus. She had a slight blood-stained discharge, brownish red in colour, and slight pain in the lower abdomen. She was told that the condition indicated a possibility of extrauterine gestation, was cautioned to keep very quiet, to remain in communication with me, and to report any developments. In the event of any pain or feeling of illness she was instructed to go to the nursing home immediately and to ring up her doctor.

In the absence of such developments she returned on June 19th, when the following condition was found.

Slight uterine bleeding as before. Slight pain in the hypogastrium. Per vaginam, the lump was found to be nearly double the size noted on the 14th. She was ordered immediately into the nursing home as a case of extrauterine gestation, and I operated on the same day, assisted by Captain H. S. Waters, I.M.S.

On opening the abdomen, there was extremely little free blood in the peritoneum, but, on raising the sigmoid flexure of the colon, the left ovary was found enlarged to the size of a peach, deep red in colour, and with loose adhesions formed by blood clot to the lateral wall of Douglas's pouch, which was subdivided into two halves by oedematous appendices epiploicae. The right half of Douglas's pouch was quite normal. The left half, besides this enlarged ovary, contained a small amount of blood-stained serum. The ovary presented exactly the appearance of a twisted ovary, or ovarian haematoma, clearly limited to the ovary, except for a shell of blood clot on the outer side.

The left Fallopian tube was entirely normal throughout its length, its abdominal ostium being patent and entirely free from any swelling or blood. On freeing the ovary a small amount of this blood clot detached itself from the outer wall of Douglas's pouch, but the ovary remained adherent to the back of the left broad ligament by the ovarian ligament. In fact, the ovary maintained its normal relation to the unaltered mesosalpinx and corresponding tube.

The ovary was resected and the ovarian ligament tied off. The right tube and ovary were both normal. The patient had specially requested the operator to leave both tubes if possible (!), and, the operation being done under spinal anaesthesia, she kept inquiring as to the condition found; for these reasons the left tube, being entirely normal, was allowed to remain. The patient made a good recovery from the operation.

The specimen was immediately examined by the operators. On incising the ovary towards its outer side a gestation sac was found deeply embedded, and, on opening this, an ovum, 0.6 cm. in length, was demonstrated.

Pathological Report.—The specimen was sent for examination by Dr. P. V. Gharpure, professor of pathology, Grant Medical College, who reports as follows.

The specimen is approximately of the size and shape of a small hen's egg, or resembling a small truncated cone, elongated and tapering at one end, and broader at the other. Near the broader end on one of the faces is an oval rough area, 3 by 2 cm., indicating attachment of the ligament, by severing which the specimen has been removed at operation. The specimen measures 5.5 by 4.5 cm. On section it exhibits a non-homogeneous wall nearly uniform in thickness, with a number of blood sinuses and interstitial haemorrhages: the wall has an average thickness of 0.5 cm. It encloses a smooth, shining cavity, lined by a smooth membrane. Inside this cavity, towards the broader end, is attached a tiny white object by a slender pedicle. This is an embryo, 4 mm. at its broadest and 1 mm. at its longest part. It has lost its "C" shape, and has a broader middle and tapering posterior end. Stalks of appendages are recognizable. The embryo does not show any formation of a face. The age, by process of exclusion, is beyond completion of five weeks but before completion of the seventh week. Its internal anatomy has not been studied.

On microscopical examination the wall around the sac contains abundant vascular channels and well-formed chorionic villi, with proper cell content. Some sections show ovarian stroma in anatomical continuity with the chorionic tissue. No localization of a formed placenta can be made out. The entire wall surrounding the gestation sac shows uniform appearances.

COMMENT

This case of ovarian pregnancy satisfies Spiegelberg's¹ criteria, which are as follows:

1. The tube on the affected side must be intact.
2. The foetal sac must occupy the anatomical position of the ovary.
3. It must be connected with the uterus by the utero-ovarian ligament.
4. Definite ovarian tissue must be found in the sac wall. This case also satisfies an additional criterion, put forward by Whitridge Williams² in the original edition of his *Obstetrics* (but not included in the latest edition), that ovarian tissue must be present in several portions of the sac wall at some distance from one another.

Although the tube was not removed, and therefore was not examined microscopically, it presented no evidence of abnormality to one who is constantly examining normal and abnormal tubes *in situ*. In this connexion it would appear theoretically necessary to remove and examine both tubes to avoid possible cases where a fertilized ovum has been extruded from one tube, and has found a nidus on the surface of the ovary of the opposite side, such cases being inadmissible as true ovarian pregnancy.

It seems likely that ovarian pregnancy does not occur in a strictly normal ovary. Alternatively, a pregnant ovary undergoes certain histological changes in its structure, with disappearance of immature Graafian follicles. From an examination of the sections of the present specimen, as well as from published illustrations and descriptions of others, it appears that in cases of ovarian pregnancy the ovary itself may be very deficient in Graafian follicles. It is to be noted in the present case that menstruation was becoming less profuse than normal.

The mechanism by which ovarian pregnancy is possible is uncertain. Probably a follicle ruptures with a pinhole

orifice, or the tension of the liquor folliculi is below normal, so that the egg-cell contained in it is not detached. A spermatozoon penetrates, and the fertilized ovum, by the erosive action of its trophoblast, burrows deeply into the ovary. In the present case, as shown in the photograph, and I think in other typical cases, the ovum is found deeply embedded in the ovary and surrounded entirely by ovarian tissue.

Dr. Gharpure, in a recent discussion, has put forward the very interesting and, I think, original view (to which he has kindly permitted me to allude), that all cases of ovarian, and many of tubal, pregnancy may be explained by minute inclusions in these organs of endometrial tissue similar to what occurs in endometriosis; such inclusions or rests would exert a chemotactic attraction for the fertilized ovum. It is possible that careful histological study may afford support for this view.

From the estimate of this ovum being of six weeks' development, it appears that pregnancy followed shortly after the Rubin test. The suggestion that a fertilized ovum, free in its passage along the tube towards the uterus, was driven back by the insufflation, and settled on the ovary must be faced, but it appears improbable (1) because one would expect to find such an ovum on the surface of the ovary rather than in its interior, and (2) because the ovum would be somewhat more advanced, just over seven weeks. Ovulation, moreover, is held to occur about the fifteenth day of the menstrual cycle—that is, about May 5th in the present case, four days after the Rubin test was performed.

Professor Gharpure and myself would be glad to lend the blocks of the ovary from which sections were made to anyone interested.

The Codex Revision Committee of the Pharmaceutical Society of Great Britain has issued four subcommittee reports. That of the Pharmaceutical Chemistry Subcommittee gives a summary of the principal standards for chemical substances recommended by it, and accepted provisionally for inclusion in the *British Pharmaceutical Codex, 1934*. The Pharmacy Subcommittee has summarized the principal new or revised formulae recommended by this subcommittee for inclusion in the *Codex*. It advises also the restoration of a number of preparations from earlier pharmacopoeias which are not in the *British Pharmacopoeia, 1932*, but are still in more or less frequent demand. For many of the preparations tests have been worked out with a view to the constitution of a *Codex* standard, and alcohol limits for the concentrated infusions, spirits, and tinctures have been noted. The hope is expressed that it will be possible to obtain the permission of the Board of Customs and Excise to use methylated spirit in making preparations not taken internally, such as liniments, paints, and ointments. The report of the Action and Uses Subcommittee summarizes the descriptions and standards submitted for the inclusion of certain substances in the *Codex*, among which are antitoxins, toxins, and gland products. The Dressings Subcommittee proposes for inclusion in the *Codex* basic materials, such as jute, silk, and wool, descriptive monographs of their characters having been prepared. In the case of such dressings as phenol gauze and tow, no quantitative standard for the proportion of medicament present has been recommended. This subcommittee's report relates, therefore, to the more important dressings for which revised requirements have been prepared. It is hoped that this summary will prove particularly useful to manufacturers and others interested in the standardization of dressings. These four reports are published by the Pharmaceutical Press, 23, Bloomsbury Square, W.C.1, the first two costing 2s. 6d. each and the last two 1s. 6d.

DIABETES MELLITUS IN ASSOCIATION WITH DEGENERATION OF THE SUPRARENAL GLANDS

BY

R. W. BROOKFIELD, M.D., Ph.D., M.R.C.P., D.P.H.

HONORARY ASSISTANT PHYSICIAN, ROYAL SOUTHERN HOSPITAL,
LIVERPOOL; LECTURER IN PRACTICAL THERAPEUTICS,
UNIVERSITY OF LIVERPOOL

AND

H. V. CORBETT, M.B., ChB., M.R.C.S., L.R.C.P.

LATE HOUSE-PHYSICIAN TO THE HOSPITAL

(With Special Plate)

The association of diabetes mellitus with gross pathological changes in the suprarenal glands is uncommon, and is of great interest from the biochemical as well as from the clinical standpoint. The case of diabetes reported below is further noteworthy because of the unusually high blood sugar values recorded and the enormous doses of insulin required during the course of treatment.

CASE REPORT

The patient was a married woman of 61 years. She was said to have been in indifferent health for about a year prior to coming under observation. During the latter half of this period there had been noticeable loss of weight and some thirst and polyuria. Three weeks before she was admitted to hospital she had a shivering attack and frequency of micturition. The urine was examined at this time, and was found to contain no sugar, nor was any other abnormal constituent detected. Thereafter she appeared to be returning to normal health, until two days before admission she became drowsy, and ultimately semi-comatose. The urine was now found to contain much sugar.

On her admission to hospital on February 21st, 1933, at 11.30 p.m., she could be roused without much difficulty, and answered questions intelligently. Her breath smelled of acetone and the urine gave a strong Rothera reaction. The ocular tension was approximately normal, but her tongue was dry, and a subcutaneous saline, given shortly afterwards, was absorbed with great rapidity. Her state of nutrition was good, and physical examination failed to reveal the presence of any infective process. The heart was moderately dilated and the pulse of low tension, with a frequency of 104 per minute. The respiratory rate was 24, but respiration was otherwise normal in character. The temperature was 97° F. Insulin (30 units) was injected intravenously forthwith and the blood sugar estimated. The high value of 1,040 mg. per 100 c.c.m. was obtained (Folin-Wu method). At 1 a.m. 100 units of insulin were given. At 4.30 a.m. the blood sugar was 935 and at 8.30 a.m. 844 mg. per 100 c.c.m. These figures were verified by additional estimations on the same samples by another observer at a different laboratory. At 10 a.m. the patient received a further 100 units of insulin. At 12.30 p.m. the blood sugar figure was 606 mg., and at 1 p.m. 100 units of insulin were again given. At 3.30 p.m. the blood sugar had fallen to 400 mg., and at 6 p.m., after a further 100 units of insulin, to 200 mg. per 100 c.c.m. By this time the urine was free from sugar and from acetone, the bowels had been well opened, and the liberal administration of fluid, with glucose, had completely relieved any dehydration originally present. At 8.30 p.m. the administration of 30 units of insulin was begun three-hourly, and by this means the blood sugar was kept within the limits 150-228 mg. per 100 c.c.m. for the next three days. In spite of the apparent complete relief of the diabetic state, the general condition of the patient had improved but slightly. She was still drowsy and incontinent. The blood non-protein nitrogen was 39 mg. per 100 c.c.m. and the Wassermann reaction negative. An attempt was made, with partial success, to maintain a fluid diet corresponding to six lines in R. D. Lawrence's scheme. On February 24th the temperature rose to 104.2° F., and the patient began to suffer from occasional rigors.

She was found to have a leucocytosis of 42,500. No other evidence of septic infection could be discovered, and the blood culture was negative. The urine contained a trace of albumin and a few leucocytes, but was otherwise normal. On February 25th the dose of insulin was reduced to 20 units three-hourly. On the 28th a blood sugar value of 75 mg. per 100 c.c.m. was recorded, though there were no symptoms pointing to hypoglycaemia, and the dose of insulin was reduced to 15 units three-hourly. On the following day, however, the blood sugar had risen to 296 mg. per 100 c.c.m., and the former dosage of 20 units of insulin was resumed four-hourly. The temperature of the patient continued to fluctuate between 98° and 104°, and her general condition slowly deteriorated. She died, apparently of cardiac failure, on March 3rd, ten days after admission to hospital.

Post-mortem Findings

A necropsy was performed, about six hours after death, by Dr. R. Howard Mole, pathologist to the hospital, to whom we are indebted for the details which follow.

The liver, spleen, alimentary canal, lungs, and heart presented no abnormality. At the site of a subcutaneous injection in the right pectoral region there was a sharply defined area of necrosis, with some subcutaneous emphysema, but little evidence of inflammatory reaction. *Cl. welchii* was isolated. The right kidney showed on its surface numerous haemorrhagic areas and a few miliary abscesses. On section multiple areas of focal congestion were visible, and a few minute abscesses. Microscopically the organ showed widespread small-celled infiltration, congestion, and fibrosis. The left kidney, both renal pelves, and the bladder were normal. The pancreas was smaller than normal. Microscopically the islets of Langerhans showed hyaline and fibrotic changes.

Both suprarenal glands were cystic, having the appearance of small semi-collapsed balloons. On section each was found to have been converted into a thin shell, which enclosed a single cavity containing a little yellowish fluid. Microscopically (see Fig. on Plate) the capsule was thickened, and the cortex showed marked changes, involving particularly the fasciculate and reticulate layers. Considerable atrophy of the cell columns of the former was noted, the columns being attenuated and broken up into small cell groups. The intervening tissue had a necrotic appearance; cell boundaries were difficult to demarcate and nuclei were absent. There was some fibrosis. The boundaries of the reticulate layer and medulla were difficult to make out. Both showed much round-celled infiltration and fibrosis, and no normal medullary tissue was seen.

Discussion

Levy Simpson² has recently collected from the literature seven cases of diabetes in which lesions of the suprarenal capsules have been found at necropsy, and has added a further case of his own to this number. In four of the cases there were no adequate grounds on which a diagnosis of Addison's disease could be made during life. The present case must also be placed in this category. In spite of the existence of advanced disease of the suprarenal capsules, the classical symptoms of Addison's disease—pigmentation and vomiting—were not observed. The patient was asthenic and lethargic throughout, and though a sphygmomanometer reading was not taken examination of the heart and pulse suggested that the blood pressure was consistently below normal. A consideration of the biochemical and pathological data suggests that, apart from the suprarenal lesion, a fatal issue would hardly have been anticipated. The condition of the blood and urine after treatment indicates that the diabetic state was completely relieved. Renal function did not seem to be greatly impaired. The day after admission the non-protein nitrogen of the blood was 39 mg. per 100 c.c.m., and a few hours before death it was 54 mg. Septic absorption from one or other of the foci of infection present may have been contributory to a fatal result, but neither the inflammatory process in the right kidney nor that in the pectoral region appeared to be of great severity, and the

condition of the organs in general did not suggest a severe toxæmia. It appears possible, therefore, that suprarenal inadequacy was an important factor in causing death.

The lesion is an unusual one. Brenner² has reviewed the literature of suprarenal fibrosis in some detail, but in none of the case reports collected by him is there any reference to a cystic condition resembling that encountered in this case. The presence of fibrous tissue argues the existence of pathological changes in the glands of some months' duration at least, and it may well be, as Levy Simpson has suggested in other cases, that the same toxic agent has produced fibrosis in both suprarenals and pancreas. It is highly probable that the cellular necrosis and the cystic condition developed acutely in glands already the seat of chronic pathological change, either as a result of the diabetic toxæmia or of toxic absorption from the inflamed areas. The presence of suprarenal inadequacy in diabetes mellitus is of particular interest in view of the antagonism which is stated to exist between the suprarenal glands and the pancreas. In uncomplicated Addison's disease hypoglycaemia is the rule (Wadi⁴). Figures as low as 70 mg. of glucose per 100 c.cm. are commonly obtained. Patients with Addison's disease are very sensitive to insulin, and a fatal result has been recorded after so small a dose as five units (Maranon⁵). This being so, it is not surprising to find that when the subject of Addison's disease suffers also from diabetes the control of the blood sugar by insulin presents considerable difficulties. In both Arnett's⁶ and Levy Simpson's² cases hypoglycaemic crises were very readily induced. In contrast, the present case showed a remarkably steady blood sugar value of about 200 mg. per 100 c.cm. once insulin control had been established, and it must be admitted that this possibly argues against there being serious lack of the suprarenal hormone.

There seems to be no explanation available of the exceptionally high blood sugar level before treatment was instituted. Still higher values, amounting to 1,400 and 1,490 mg. per 100 c.cm. respectively, have been recorded by Joslin⁷ in two fatal cases. The massive doses of insulin required to bring the blood sugar back to the normal level are almost certainly related to the high initial blood sugar value. In the first twenty-four hours of treatment 460 units were given, for the next three days 240 units daily, and thereafter approximately 160 units daily. On one day, when the dose was reduced to 120 units, the blood sugar again rose to 296 mg. per 100 c.cm., indicating that the doses previously given were not unnecessarily large. As there was no rise of temperature until the third day after admission to hospital, by which time the blood sugar had been reduced to 200 mg. per 100 c.cm., neither the high blood sugar nor the necessity for the large doses of insulin can be ascribed with certainty to the presence of infection.

SUMMARY

A case of diabetic coma is reported in which exceptionally high blood sugar values were encountered, necessitating the administration of enormous doses of insulin.

At necropsy an advanced degenerative lesion of the suprarenal glands was discovered, and the bearing of this on the course of the patient's illness is discussed.

REDUCTION OF FRACTURES OF THE SURGICAL NECK OF THE HUMERUS

BY

H. MORTON ANDERSON, M.B., CH.B., F.R.C.S.ED.
SURGEON TO COVENTRY AND WARWICKSHIRE HOSPITAL, COVENTRY

(With Special Plate)

The reduction of fractures of the surgical neck of the humerus often presents considerable difficulty. Resort to open reduction may be necessary, but one is naturally unwilling to adopt such a procedure unless compelled to. The method here suggested is offered as an alternative worthy of trial in cases in which the ordinary methods of reduction have proved unsuccessful.

The chief difficulty in this type of fracture is in obtaining fixation of the abducted head during the manoeuvre of reduction, and if this can be attained manipulation becomes considerably simplified. It is possible to do this, however, by the simple method of partial

transfixion of the head of the bone by a bone-awl passed through a stab incision on the outer aspect of the shoulder.

The subsequent steps in the procedure are carried out under the screen in the x-ray department. These consist, in the first place, of traction of the limb in the adducted position in order to pull the lower fragment down to the level of the upper, and, while maintaining this pull, adducting the arm across the chest. The abducted or upper fragment is now adducted by depressing the handle of the bone-awl. It is then easy to engage the upper end of the lower fragment in the fractured surface of the upper. Lastly, the arm is slowly brought back to a slightly abducted position, where it is maintained by splints. Once accurate approximation of the two surfaces is obtained there is little tendency to slipping of the fragments.

The accompanying diagrams will perhaps make it easy to understand what has been described in the text. The manoeuvre is simple and very satisfactory, and its various phases can be completely controlled on the screen.

Photographs—before and after—of an actual case treated by this method, are shown in the figures reproduced on the photogravure plate.

CARCINOMA OF THE OESOPHAGUS

A METHOD OF TREATMENT BY MEANS
OF RADON SEEDS

BY

T. B. JOBSON, M.D., D.P.H.

SURGEON FOR EAR, NOSE, AND THROAT

AND

G. H. STEELE, M.S., F.R.C.S.

ASSISTANT SURGEON

ROYAL SURREY COUNTY HOSPITAL, GUILDFORD

(With Special Plate)

Apart from a few brilliant but unhappily isolated cases of radical excision, it is generally recognized that the successful extirpation of carcinoma of the thoracic oesophagus by operative measures is a virtual impossibility, and that the operative mortality is in the region of 100 per cent. It would be expected that these growths, being in the main typical squamous epitheliomata, would respond as well to radium treatment, as do growths of the tongue and lip; but this hope of cure has been in no way justified, although recent results from deep x-ray therapy have been very encouraging. It therefore remains to decide which of the various palliative measures will, with the minimum amount of discomfort, give the unfortunate patient the greatest relief from his symptoms for the longest period, and at the same time hold out a hope, however slight, of cure.

The outstanding symptom of carcinoma of the oesophagus, and the one calling most urgently for relief, is, of course, dysphagia. Before the advent of radium, gastrostomy was practically the only recognized treatment, although successful palliation was reported as a result of dilatation of the stricture, with or without the help of intubation. Patients with a well-performed gastrostomy can get along very well, and may have many months of comfortable existence to which to look forward, but obviously they are better off if the patency of the oesophagus can be restored.

USE OF RADON

The first applications of radium in cases of carcinoma of the oesophagus were made with the help of containers, with the appropriate dose of radium, lowered into position in the lumen of the gullet and subsequently removed. More lately, methods of thoracotomy and trans- or extra-pleural application of radium or radon to the outer surface of the oesophagus have been tried, with the obvious disadvantage of requiring a serious major operation in a debilitated patient in order that access may be had to the growth. The method about to be described is simplicity itself—direct implantation of radon seeds into the growth through an oesophagoscope. This necessitates a long seed introducer which will not interfere with the limited field of vision allowed by the oesophagoscope, and such an instrument has been designed by one of us (T. B. J.). It consists of an elongated trocar and cannula, with the handle conveniently attached to the side, the knob of the trocar being levelled off flush with the barrel of the cannula. The proximal end of the cannula is marked in alternate centimetre lengths of black and white, as an indication of the depth to which the point of the instrument has penetrated after contact with the growth, the distance being checked against the level of the proximal end of the oesophagoscope. There is no magazine for seeds, as this is unnecessary on account of the small average number of seeds used and would only complicate the instrument. The introducer can be made

in any length, but we find that it is most convenient to have three sizes, long enough to protrude 5 cm. beyond the mouth of (1) the long, (2) the medium oesophagoscope, and (3) the direct laryngoscope, respectively. A blunt-ended plunger with which to push home the seeds accompanies each introducer.

If the patient is in a really serious condition as a result of starvation, a preliminary gastrostomy is performed under local anaesthesia in order to feed him up and render him fit for the oesophagoscope. If he is reasonably well the gastrostomy is omitted. After x-ray examination of a barium swallow has been made to ascertain the level and extent of the growth, and to exclude conditions such as achalasia of the cardia, oesophagoscopy is performed under general anaesthesia; the use of an intratracheal catheter ensures a quiet anaesthesia unimpeded by the pressure of the oesophagoscope behind the larynx, and saves the operator from a continuous blast of anaesthetic in his face. Latterly we have used intravenous sodium evipan as the sole anaesthetic, and with very satisfactory results.

The oesophagoscope is passed down to the growth, which is easily recognized by its raised and everted edge, and a portion is removed for microscopical examination. Then, or later if it is desired to wait for the result of the biopsy, the cannula is pushed into the growth for a distance of 1.5 cm. and a seed inserted; the cannula is withdrawn 1 cm. and another seed deposited. This procedure is repeated at six equidistant points around the

lumen of the gullet, the object being to produce a double ring of seeds encircling the growth (see Plate, Fig. 1). The seeds used are of 1.5 millicuries, screened with 0.5 mm. platinum. The patient is x-rayed after operation, and it is usually found that nine or ten seeds are still in position, the missing ones presumably having been inserted back into the lumen of the gullet below the stricture. The patients suffer no post-operative discomfort, and need not stay in hospital for any length of time, being discharged as soon as they have recovered from the effects of the anaesthetic.

An obvious danger of this operation is that it is impossible to tell where the point of the instrument is when it has been introduced to the full extent. From the literature it appears that accidental rupture of the oesophagus by an oesophagoscope is almost invariably fatal; but that the danger of perforation by a small-bore cannula is of slight degree is shown by the fact that we have, to our certain knowledge, penetrated the oesophageal wall on four occasions without harm. Twice we have observed a strong spurt of blood from the proximal end of the cannula, and a spurt from an 80 mm. tube of 1 mm. bore can only have been produced by the point entering the aorta; and twice radon seeds have been demonstrated by x rays in the pleural cavity at a considerable distance (see Plate, Fig. 2); in none of these cases was any ill effect noticed. The only alternative to this apparently not very grave danger would be to introduce one ring of seeds at a depth of 1 1/2 cm. only, in which case only about 1 cm. length of oesophagus would be irradiated instead of 2 cm., and in such a deadly disease any slight additional risk is worth taking if it is in any way going to improve the prognosis. It will also be contended that only a short length of gullet can be irradiated, but if the growth extends for more than 2 cm. the probability is that it has extended beyond the oesophagus, and no method will cure it.

RESULTS

Up to the present we have treated sixteen cases in this way, a total, of course, far too small from which to draw satisfactory conclusions. The growth is not visible or palpable in the whole of its extent, to allow of accurate dosage and placing of seeds, so that the treatment is largely empirical. But we are of the opinion that an operation of such slight magnitude is well worth performing, as gastrostomy or dilatation of the stricture resulting from the healing of the cancerous ulcer is always available as a second line of defence. So far, there have been no deaths resulting from operation, and the immediate results are sometimes little short of miraculous, the patient volunteering evidence of marked improvement in swallowing at the end of a fortnight or three weeks, although the dysphagia may return later. Other cases fail to respond from the start; but against this may be set off the fact that in a large number of cases the growth is so advanced as to shorten life as much by cancerous cachexia as by starvation, and has already extended beyond the wall of the gullet. In fact, one fairly healthy-looking man, with a six months' history of dysphagia, refused operation, and was dead a fortnight later; had he consented, he would, of course, have been classified as a bad result. Our best case is alive and well three years after operation, swallowing normally, and gaining weight. Two others lived for fifteen and eighteen months respectively, with a degree of swallowing in one case approximating to normal, and in the other within the limits of comfort and sustentation of weight. Three patients were able to remove their gastrostomy tubes, which had been used previous to operation. One patient who was brought into hospital on the verge of death from starvation and thirst lived for fifteen months after removal of his gastrostomy tube following irradiation.

The question arises as to whether it is better to leave a gastrostomy tube once it has been inserted, in case the oesophagus closes up again, or to remove it if irradiation is successful and risk having to reopen the fistula. We have found it better to put it to the patient, and let him decide. In some cases the patients were submitted to further oesophagoscopy, and in each case the growth was found to have disappeared and to be replaced by a smooth scar; if there was a stricture, it was amenable to dilatation with oesophageal bougies under direct vision. We have had the opportunity of making a post-mortem examination on only two of our cases. One patient died nine months after operation from erosion of his aorta by the growth, which was found to have recurred extensively, together with a chain of secondary glands extending upwards into the neck; incidentally, this was not one of the cases in which the aorta had been penetrated by the introducer. The other died after two months, the growth having spread to the lung and involved the glands.

STATISTICAL SUMMARY WITH SHORT CASE RECORDS

Number of cases treated	16
Alive and well (three years)	1
Lived more than one year	2
Considerable temporary relief	11
Not relieved	2
Able to remove gastrostomy tube	3

Specimen Cases

R. A., 62. Three months' dysphagia. Biopsy: squamous epithelioma. Ten seeds to growth at level of D 7. Two years later: "Quite well, swallows ordinary food, has gained weight." Three years after operation: "Still swallowing well; at work."

W. S., 75. Three months' dysphagia. Admitted in the last stages of starvation and thirst, unable to swallow fluids for forty-eight hours. Gastrostomy. One month later radon to growth at level of D 8. In one week could swallow

liquids; in two weeks could take cornflour and gruel. Re-oesophagoscoped—healed scar. Refused dilatation, preferred to keep gastrostomy tube to supplement mouth feeds. Lived fifteen months.

J. F., 55. Two months' dysphagia. Fluids only. Gastrostomy. Radon to growth at level of D 4. Oesophagoscoped one month later—healed scar on left side, growth still present on right. Twelve more seeds. Gastrostomy tube removed one month later, because swallowing was so good. Died nine months later of erosion of aorta by growth, following reopening of gastrostomy.

R. S., 71. Four months' dysphagia, semi-solids only. Radon to growth at level of D 5. Six months later can swallow bacon and egg, which he seems to prefer for all meals. Oesophagoscoped—healed scar which dilates well with bougies. Is coming up again for further dilatation. The improvement in swallowing was not evident until a month after operation, and we were correspondingly despondent. It is much too early to be optimistic about this case, but the outlook at present is hopeful.

A. G., 68. Five months' dysphagia, soft solids only. Radon to growth at level of D 8. One month later could swallow cheese, bread-and-butter, and fish. Died four months later. This is a typical instance of the temporary improvement observed in the majority of cases.

S. M., 80. Four months' dysphagia, fluids only. Radon to growth at level of D 4. No improvement. Oesophagoscoped two months later; growth smaller in size, but not much altered in appearance. Stricture very tough, will not dilate up. Refuses gastrostomy.

A CASE OF VON RECKLINGHAUSEN'S DISEASE

BY

WILLIAM MARSHALL, M.B., CH.B.

HONORARY SURGEON, PETERBOROUGH AND DISTRICT MEMORIAL HOSPITAL

With a Note on the Psychology

BY

ALEXANDER W. WATT, M.B., CH.B., D.P.M.

(With Special Plate)

Below I append some notes on a complete case of von Recklinghausen's disease, occurring in a man who was also the subject of a right inguinal hernia, which required operation by an unorthodox incision.

He was an agricultural labourer, aged 57, who first noticed some nodules on his chest when he was 16. He could give no family history of a similar condition, but he had not kept in touch with his relatives. He had been twice married, and had a family of nine children, the two eldest of whom, girls of 20 and 15, were stated to have pigmented patches on the dorsum of the forearm.

The whole of the anterior and posterior aspects of his thorax and abdomen were covered with typical nodules—soft, with firm centres, sensitive to touch, and ranging in size from a pea to a hen's egg. There were also nodules on the face, and the scalp was covered with them. The arms and legs were affected to a lesser extent, and there were small nodules on the palms of the hands and the soles of the feet. "Blue spots" were numerous on the flexor aspects of the arms. There was a pigmented area 2 in. square on the medial aspect of the left thigh. There was well-marked bronzing of the skin, especially of the face. The hair of the scalp was markedly coarse. There was none on the chest, but the pubic hair was of the normal adult male distribution. There were no patches of adipose deposit.

Notes on the other systems affected are as follows:

Nervous.—There were no neurological signs or symptoms beyond a slightly increased left-knee jerk, and a left-sided deafness of the conduction type.

Endocrine.—The features were suggestive of the acromegalic type, and the supraorbital ridges were marked. The radiogram showed a definitely deepened sella turcica, but there was no

diminution of the visual fields. There was no glycosuria and no polyuria. Basal metabolic rate by Read's formula was +3. The condition suggested a dyspituitarism—an earlier increased function now being masked by hypopituitarism. The bronzing was not Addisonian—there was no asthenia, the mucous membranes were not affected, and the systolic blood pressure was 130. There was no obvious thyroid dysfunction.

Skeletal.—There was a well-marked scoliosis, convex to the left, extending from the sixth thoracic to the fourth lumbar vertebra. There was some expansion of the head of the left fibula without definite cyst formation.

Psychological.—I am indebted to Dr. A. W. Watt for the following notes, as well as for many helpful suggestions. "The patient is an introvert. Docile in disposition, and serene in temperament, he has no false modesty about his appearance, and no resentment against it. He is companionable, but not sociable, in that he does not actively seek the society of others, but, when included, enjoys their company and conversation, giving them his undivided attention and reasoning to the best of his limited intelligence, which is equivalent to that of a child of 15. Emotionally he is quietly

euphoric, and his attitude to life is stable, equable, and submissive. He expects little from the future, and is content with the past.

The patient was admitted because the dragging pain of his hernia was interfering with his work. The presence of the nodules ruled out any possibility of a truss. In view of the statement (Dick and Illingworth: *Textbook of Surgical Pathology*) that the nodules, if incised, tend to become malignant, the orthodox incision was out of the question. Fortunately the skin of the thigh had comparatively few nodules and was very elastic. An incision was therefore made 3/4 in. below, and parallel to, the inguinal ligament, and the skin retracted over the ligament to give access to the canal. The usual Bassini operation was performed. No nodules were discovered under the skin. Recovery was uneventful, except that the nodules on his back tended to become red with lying in bed.

I am indebted to the house-surgeon, Dr. J. Ivor Williams, for his careful note-taking and advice in posing the photograph.

HYPODERMOLITHIASIS

BY

J. PATERSON ROSS, M.S., F.R.C.S.

ASSISTANT DIRECTOR, SURGICAL PROFESSORIAL UNIT, ST. BARTHOLOMEW'S HOSPITAL

(With Special Plate)

The term "hypodermolithiasis" might be expected to refer to any deposit of stone-like material in the subcutaneous tissue, and to include gouty tophi, and calcification in tuberculous foci, cysts, and tumours in, or just beneath, the skin. There is a tendency, however, to limit the use of the term to cases in which subcutaneous calcareous nodules are formed in the absence of any such antecedent skin lesions.

Though calcareous concretions in the skin were described as long ago as the middle of the seventeenth century, the account of a case published by Weber,¹ a Swiss physician, in 1878, is commonly considered to be the earliest record. The close similarity between these concretions and the tophi of gout may be misleading, and it appears that Weber at first mistook calcareous for uratic deposits. The introduction of radiography has eliminated this error, for tophi are not opaque to x-rays. The incidence of hypodermolithiasis is difficult to estimate because it seems likely that the disease may sometimes go unrecognized. Five years ago Köhler,² who was evidently careful to exclude cases in which calcification occurred in the deep tissues as well as in the skin, could discover records of only twelve cases, but the number is being steadily increased, especially in the French literature, largely owing to the influence of Thibierge and Weissenbach.³ The present account is being published not merely to bring forward three more examples of a clinical and pathological curiosity, but in order to suggest a method of treatment which appears to be worthy of trial, though an opportunity of putting the matter to the test has not yet presented itself.

CASE RECORDS

Case I

A woman, 28 years of age, complained that her right thumb was becoming larger, her attention having been drawn to it because she was unable to buy gloves that would fit. She is a dispenser, and though she suffered no pain, yet as the swelling of the terminal phalanx of the thumb increased she became aware of slight awkwardness in handling large bottles. At a later date a firm lump appeared in the pad of the left middle finger. Her general health was excellent, but in childhood she had suffered severely from chilblains, and for many years cold had caused the fingers of both hands to "go

dead," an affliction which she had inherited from her father. The effect of exposure to cold was that all the fingers became very cold and pale from end to end, but even during the period of recovery they never became blue. Her sister's fingers reacted similarly, but as she took up cookery her employment provided the ideal conditions for counteracting this inherited tendency to "dead fingers." Dispensing, on the contrary, involves the handling of cold objects, and our patient noticed how the pressure exerted through the pad of her right thumb when grasping a large bottle would cause more intense pallor of this particular part.

On examination the radial pulses were equally full, and the arterial wall felt normal. When warm the skin of the fingers had the natural pinkish hue. It was soft and pliable, and there was no ulceration or scarring. The terminal phalanx of the right thumb was enlarged, owing to a firm, ill-defined swelling or induration on its palmar aspect. The induration seemed to lie immediately beneath the skin, but there were no signs of inflammation, nor were there any white spots visible on its surface. At the tip of the left middle finger there was a similar but much smaller indurated swelling, and at one point a hard, whitish substance seemed to be about to burst through the skin. There were no signs of disease elsewhere in the body.

A radiogram of the hands showed two very clearly defined aggregations of calcareous nodules, in the pad of the right thumb and at the tip of the left middle finger. The bone shadows were of normal density, and there was nothing to suggest a transference of calcium from within the bones (see Fig. 1 on Plate). Estimation of the calcium and phosphorus content of the blood gave normal figures—calcium, 9.9 mg. per 100 c.cm. serum; phosphorus, 3.4 mg. per 100 c.cm. plasma.

On March 20th, 1933, the nodules were excised, and it was found that they consisted of small collections of a gritty and cheesy white substance, embedded in tough fibrous tissue. They were examined by Dr. G. A. Harrison, who reported that they consisted of amorphous matter only, no sodium binate or other crystals being present, and that they were composed of calcium phosphate with a trace of calcium carbonate.

I was at a loss to explain the condition until Dr. George Simon drew my attention to a paper by Twining and Addey,⁴ illustrated by a radiogram showing a precisely similar picture. The patient they described was a woman, 48 years of age, who had always suffered from a bad circulation, the hands and feet becoming cold and blue in cold weather, or when immersed in cold water. Twelve months previously she began to have pain at the tip of the middle finger of the right hand, and after six months a swelling appeared, showing through the skin as a yellowish "blister," which, when pricked, exuded yellowish-white matter. X-ray examination revealed calcified nodules in the index and little fingers as well

as at the tip of the middle finger. It will be noted that this patient's fingers became blue when exposed to cold, but the occurrence of pallor without cyanosis, as in our case, has been recorded by Scholefield and Parkes Weber.⁵ The early history of their patient, a woman aged 50, was exactly similar to that of ours, for as a child she had been subject to chilblains, and at about the age of 20 she began to be troubled by the fingers "going dead" in cold weather. The morbid anatomy was also identical, removal of one of the subcutaneous concretions proving a difficult matter "because it was firmly embedded in a dense meshwork of fibrous tissue." Since the age of 35 years the skin and soft parts of the fingers had been becoming harder and stiffer. The appearance of sclerodactylia is the only significant difference between Scholefield and Parkes Weber's case and ours, and may be explicable by the difference in their ages. The fact that our patient had the characteristic nodules while the skin and subcutaneous tissue elsewhere were of the natural texture may be of importance, because it seems to show that calcification can occur merely as a result of the vasomotor phenomena associated with "local syncope" and pallor of the skin. Scholefield and Parkes Weber inferred from the history of their patient that the process of calcareous deposition commenced about the same time as the sclerodactylia, but were inclined to think that calcification was really secondary to the sclerosis.

Case II

In June, 1933, Mr. R. C. Elmslie referred to us a patient with Raynaud's disease from whose fingers he had curetted out calcified nodules. She was 52 years of age, and had suffered from Raynaud's disease for thirty years, but as she had spent the greater part of her life in a warm climate the disability had been minimal. In November, 1929, and again in June, 1933, calcareous concretions had been removed from her fingers, but a radiogram showed that there were many smaller nodules still present (see Fig. 2 on Plate). Though the Raynaud's disease involved the feet also, x rays did not reveal any calcification in the toes, this observation being in agreement with other published reports.

Case III

A woman, 62 years of age, was referred to us by Dr. H. Morley Fletcher in October, 1933. For twelve years she had suffered from attacks in which her fingers and toes became blue and felt numb. The attacks were brought on by cold, and the pulse in the radial arteries was normal. In addition to these manifestations of Raynaud's disease, the fingers presented the appearance characteristic of sclerodactylia, the index and middle fingers of both hands being particularly indurated and stunted, with atrophic pads and with nails which curled over their tips. For five years she had noticed numerous firm lumps under the skin, which formed first in the fingers, then in the palm, and finally all along the ulnar border of the forearms, as far as the elbows. As they grew larger they became yellow, and when she pricked those which looked as though they were about to penetrate the skin, some cheesy white substance escaped. X-ray examination revealed calcified masses in all the digits, in the skin of the palm, and along the ulnar border of the forearm on both sides. Some of the terminal phalanges showed the bone destruction which is not infrequent in advanced Raynaud's disease, but elsewhere the bones showed no evidence of decalcification (Fig. 3 on Plate).

Discussion

Subcutaneous calcareous concretions in Raynaud's disease have been recorded by Haldin Davis,⁶ in a woman aged 34, who had suffered from chilblains all her life, Raynaud's disease for many years, and nodules in the fingers of both hands for seven years; and also by Logan,⁷ in a woman 60 years of age, whose hands and feet had been unduly susceptible to cold for as long as she could remember, and whose symptoms for fifteen years had been severe enough to warrant the diagnosis

of Raynaud's disease. The patient described by Haldin Davis had nodules on the elbows also. Another case published by Hunter is quoted by Durham.⁸ The result of chemical analysis of the concretions is mentioned by Scholefield and Parkes Weber, and by Logan. The nodules were all composed of a mixture of calcium phosphate and carbonate, but whereas the former found chiefly carbonate, Logan's analysis seems to agree with ours, which showed that the nodules consisted mainly of calcium phosphate.

It will be noticed that the cases of hypodermolithiasis quoted above have certain features in common. The patients were all women whose peripheral blood vessels were unduly susceptible to cold, and the deposits of calcium phosphate occurred in the subcutaneous tissue of those portions of the upper extremity which are naturally the coldest. There is nothing to suggest a disturbance of calcium metabolism, and the condition appears to be purely a local disorder resulting from impaired blood supply and malnutrition of the subcutaneous tissue. This group must therefore be distinguished from the more widespread calcareous deposits which may occur when the metabolism of calcium is faulty. Even the calcareous concretions rarely found in scleroderma, which have been so fully studied by Durlum,⁹ and those with which we are now dealing are probably not identical. The chemical reactions which underlie calcification are not perfectly understood, but it is a matter of experience that the tissues affected are almost always dead or dying, and the frequency of calcification as a senile change indicates the importance of feeble nutritive activity and a retarded blood stream as causative factors. It may be that carbon dioxide holds the earthy salts in solution in the blood and lymph, and that when the stream becomes greatly slowed carbon dioxide escapes from it and the calcium salts are precipitated. An alternative theory is that put forward by McGowan,¹⁰ who believes that all calcification is based upon necrobiotic degenerative changes in which the phospho-lipines are broken up, the phosphoric acid thus set free being neutralized by calcium from the blood and deposited as calcium phosphate. Whatever the true explanation of calcification may be, it seems necessary to postulate tissue degeneration, which, in the case of hypodermolithiasis, might well be the result of the local vascular disorder.

Bearing in mind the observation that the subcutaneous calcareous concretions are associated with some impairment of the peripheral circulation, it is not unreasonable to suppose that in an early stage the progress of the malady might be arrested by means of sympathetic ganglionectomy. This treatment has been advocated in Case I, but the patient feels that her disability is not sufficient to justify the operation. The vasomotor reactions would have to be carefully tested in order to forecast the result of sympathectomy in every case, and it is probable that patients who have extensive sclerodactylia and those with Raynaud's disease who have had repeated ulceration of the fingers might prove to be unsuitable. But if it be accepted that hypodermolithiasis signifies progressive tissue degeneration, then every effort should be made to improve the circulation early in the disease.

Clinical Memoranda

A CASE OF MULTIPLE HYDATID DISEASE

(With Special Plate).

The following notes of a case of multiple hydatid disease are, we consider, worthy of publication.

A patient, aged 59, who had spent practically all his life at sea in all parts of the world, including the Far East, Australia, West Africa, and South America, consulted one of us in November, 1931, on account of dyspepsia. For some time he had been troubled with flatulence and pain in the epigastrium two to three hours after meals. His bowels were normal. He had lost about one stone in weight in the last few months. On examination his stomach was somewhat dilated, and a hard, palpable lump, which was dull to percussion and which moved on respiration, could be felt under the left costal margin. As a notch could be felt on its anterior border its position and shape suggested an enlarged spleen, particularly as he had suffered a lot from malaria while in West Africa. He was somewhat anaemic, though the blood picture did not disclose anything more than a secondary anaemia. Clinically his lungs were clear.

He was lost sight of until March, 1933, when he developed influenza. This was followed by a persistent, hacking cough, with copious expectoration, which eventually became blood-stained. Periodically he had slight attacks of haemoptysis. There was little in the way of physical signs in the chest, except some impaired resonance at the left base. The sputum was examined for tubercle bacilli and reported negative. He had lost 12 lb. in weight since first seen in November, 1931. The abdominal "tumour" had considerably increased in dimensions, and now extended almost to the middle line and downwards to the level of the umbilicus. The swelling was rounded and fluctuating, and a distinct thrill could be made out. It was now obvious that what we were dealing with was a hydatid cyst of the spleen. In May of this year, while coughing, the patient expectorated what he described as "a white skin," which was about two inches in diameter; this, in all probability, would be a small hydatid cyst.

Radiograms of the chest showed a rounded dense area situated in the upper and outer portion of the lower lobe of the right lung. In the left lung a similar shadow was seen in the upper lobe just below the clavicle. This shadow was of varying density, and suggested a lobulated cyst. A large shadow was seen involving the base of the left lung, and within it a smaller and denser shadow, suggestive of a cyst and daughter cyst (see figure on Plate). The level of the left side of the diaphragm was seen to be raised, as if pushed up by an intra-abdominal tumour or cyst. The oesophagus and trachea appeared to be displaced to the right. A barium meal was given, and the whole of the stomach was seen to be displaced to the right of the mid-line, and the position of the oesophagus, as seen in the screen examination of the chest, was confirmed. A dense area was seen in the upper and left part of the abdomen. The x-ray findings suggested multiple hydatid disease of the lungs, plus a hydatid cyst within the abdominal cavity, probably arising from the spleen.

The diagnosis of hydatid cyst was confirmed by operation. On July 5th, 1933, under spinal anaesthesia, laparotomy was performed by an incision through the upper part of the left rectus muscle. On opening the peritoneum a large globular swelling, surrounded by omentum, presented at the wound. The peritoneal cavity was packed off, and through a bloodless area a large trocar was inserted into the cyst, and almost three pints of a clear, homogeneous fluid were withdrawn. The puncture was enlarged, and eventually a large solitary mother cyst, about the size of a newborn child's head, was delivered. The cavity was swabbed with 1 per cent. formalin solution, and marsupialized to the abdominal wall. No daughter cysts were present, but examination of the lining of the cyst wall showed them in process of "budding." Convalescence after operation was normal, except for the presence of copious frothy expectoration and a slight evening rise of temperature. Sixteen days after the operation a rise in temperature to 103° was associated with the birth of a medium-sized cyst through the abdominal sinus. Three

weeks later the patient had a rigor, and next day another cyst was found projecting through the operation wound. Its removal was followed by a free discharge of purulent hydatid fluid.

The patient now made satisfactory progress until September 13th, when he had a severe rigor. He developed a rusty "spit," complained of acute pleuritic pain, and physical signs of a left basal pneumonia supervened. While expectorating on two occasions a small cyst was "brought up," each about the size of a ping-pong ball. He appeared to develop a crisis on the fifteenth day after the rigor, although the lower half of the left lung was then absolutely dull to percussion, with complete absence of breath sounds. By this time the abdominal sinus was almost healed. For eight days his temperature remained normal. On the ninth day after the crisis the temperature again commenced to swing, and the area of dullness increased, causing a good deal of dyspnoea. An exploring syringe was inserted, and thin yellow pus withdrawn to confirm the presence of an empyema. Under local anaesthesia, using 1 per cent. novotoc, rib resection was performed. The pleural cavity appeared to be almost obliterated by adherent subjacent lung. On exploration the finger found its way into a large cavity—apparently in the lung substance. Almost immediately there was a copious discharge of pus by the mouth. On withdrawing the finger from the wound a small hydatid cyst came away, a quantity of fetid pus, and another enormous cyst wall.

The rapidity with which the abscess in the lung evacuated itself unfortunately produced symptoms of acute cardiac distress, and the patient succumbed soon afterwards.

Ulverston. RICHARD FAWCITT, M.B., Ch.B.

A CASE OF OS INTERMETATARSEUM

(With Special Plate)

The following case is of interest in view of that published by Mr. Harold Dodd in the *Journal* of October 28th, 1933 (a case of "march foot"), in that it shows the architectural defect which he describes, associated with a rare example of accessory bone.

The patient, a hospital maid aged 23, had not complained of any foot trouble until two weeks before she was seen, when she was convalescent from an attack of influenza. Clinically she is a well-developed and healthy type. Both feet showed a degree of pes cavus, and an unusual mobility of the inner part of the foot in the region of the tarso-metatarsal joints was apparent on manipulation. The pain complained of was related to the inner aspect of the arch, and this was definitely tender on pressure, but there was no evidence of swelling. The x-ray appearance (see Plate) is an unusual and interesting one. The condition is bilateral, and identical on the two sides. The radiogram shows the same features as in Mr. Dodd's case—namely, apparent prolongation of the space between the bases of the first and second metatarsals through the first and second cuneiforms to the scaphoid. In addition to this, the case shows the presence of a small accessory bone lying in the proximal part of the first interosseous space. This I take to be an example of the os intermetatarsum which has been described by Köhler,¹ who gives a résumé of previous cases. The shape of the accessory bone is suggestive in that it shows a broad base, which articulates with the outer aspect of the base of the first metatarsal, and a narrow extremity, tapering towards the distal end. The condition is apparently a developmental abnormality of the nature of a vestigial accessory digit. In comparing this case with that reported by Mr. Dodd the question arises as to whether the condition he describes is a less well differentiated degree of a similar condition to the above.

Reviews

MENTAL DEFECT

In order to avoid any misunderstanding which might arise from its title, it should be stated that *Mental Defect*,¹ by Dr. LIONEL S. PENROSE, does not profess to be a systematic textbook on this subject. It is the first volume of a new series of textbooks on social biology edited by Professor L. Hogben, and it is written from this standpoint, being intended for medical and lay persons who desire to obtain information on some of the scientific problems associated with the study of mental deficiency. Dr. Penrose considers, very rightly, that among the most important of these problems are those relating to the nature and cause of mental defect. He therefore chiefly concerns himself with these, together with certain methods of scientific investigation and with a discussion of some current views. Considering the purpose of the book, less attention is naturally given to describing the various clinical types and to problems of treatment, although it is probable that sufficient is said under these headings for the reader for whom the book is intended.

The subjects of the causation and classification of defect are intimately connected, and the author discusses classification in some detail. This is rendered all the more necessary for the reason that, although the mental specialist has for long recognized the existence of many clinical forms of defect, each of which may possibly differ in its causation, the majority of lay persons, and perhaps even some medical men, are still under the impression that mental defect is a single entity and a clearly defined condition. As a matter of fact there is one type of primary amnesia, designated by Lewis "subcultural," which, strictly speaking, may not be pathological at all, but merely the tail end of a normal variation.

The author's predilections, not unnaturally, have caused him to pay more especial attention to certain aspects of the subject than to others. Unfortunately, this tends to result in his presentation being somewhat one-sided and lacking in balanced proportion. Thus, while eleven pages are occupied with a discussion as to the relationship between size of head and intelligence, to reach the conclusion that the correlation is on the whole too small to be of any practical diagnostic value, the more important and fundamental question of the relationship between cerebral architecture and intelligence is dismissed in a very cursory manner. To state that "our knowledge of the relationship between the structure of the cerebral cortex, as revealed by the microscope, and the intelligence, as ascertained by mental tests, is extremely limited," is to give an inadequate and erroneous impression of the value of the researches in this field which have been made by J. S. Bolton and other workers. Further, it is surely unjustifiable to make the somewhat sweeping assertion that "if histological examinations were carried out systematically on the brains of mental defectives with I.Q. above 50, it seems highly improbable that any large proportion would show characteristic pathological changes." Our knowledge of the cerebral histology of amnesia is still very incomplete; and this is all the more reason why systematic investigations should be made; but it is unscientific to attempt to forecast the results until this has been done. It is quite possible that such investigations might throw at least as much light upon causation as do genetical and statistical inquiries.

With regard to these latter, to which the author devotes a considerable amount of space, the results are at present

far from conclusive. While there is no doubt that inheritance plays an important part in the production of mental defect, we really know very little as to either the nature of the underlying germ mutation or the mode of transmission. This being so, the really scientific method should be the collection of as complete data as possible regarding the patient's make-up as revealed by the fullest inquiries into his family history; we are consequently unable to accept Dr. Penrose's dictum that "the value of the family history depends on the completeness with which the individuals in a given generation are studied. It is far more useful to have accurate knowledge of the sibship and parents of the patient alone than to have any amount of information about cousins and grandparents."

The book is pleasantly written and very readable, although the absence of a subject index is a disadvantage. There is much in it which should prove of interest to the general reader; yet on the whole it is somewhat disappointing. It may be that we expected too much; for the biological problems presented by mental defect are probably too great and too complicated to be explicable entirely in terms of genetics and mathematics. But we cannot help feeling that the author might perhaps have been wiser to defer publishing his views until further research into the many aspects of this very intricate subject enabled him to do so in a more conclusive and comprehensive manner.

PATHOLOGY OF THE HEART AND VESSELS

The tenth section of the new treatise of medicine published by Masson et Cie consists of two volumes, entitled the *Pathology of the Heart and Vessels*.² Professors ROGER VIDAL, and the late Professor TEISSIER are the editors. The matter has been prepared by numerous authors. The result is two large and heavy tomes of some 1,700 pages in all. All aspects of cardiovascular disease are considered, as well as the pathology. The first volume deals with the methods of examination of the heart, the study of different syndromes, and the action of drugs on the heart; the second volume, with the various diseases of the heart; and the third, yet to appear, with diseases of vessels.

On the whole the orthodox lines of teaching are followed, and a mere catalogue of the contents of this work can serve no useful purpose. In books of this kind, however, authors are apt to allot to subjects of particular interest to themselves more space in relation to other matters than their importance warrants. Or it may be that they consider such subjects to be insufficiently stressed in the ordinary textbook. For example, in the section on auscultation in the first volume the editors have given twice as much room to functional murmurs as they have to those of organic origin. The radiological examination of the heart has been covered in as few as some twenty pages: there is no illustration of the enlarged left auricle in the right anterior oblique position, and its relation to the oesophagus is not mentioned. Nothing is said about the x-ray findings in coarctation of the aorta. Electrocardiography is fairly comprehensively treated, though its presentation leaves much to be desired. Bundle-branch block is included as an arrhythmia, and extrasystoles appear under the heading of "Arrhythmies Hsiennes." The section on heart failure is unnecessarily complicated. Subacute infective endocarditis is discussed in connexion with right heart failure; then follow sections on left heart failure and auricular failure. It seems out of place to introduce into this part of the book

¹ *Mental Defect*. By L. S. Penrose, M.A., M.D., Research Medical Officer, Royal Eastern Counties Institution, Colchester. London: Sidgwick and Jackson. 1933. (Pp. xi + 183; 4 plates and 2 figures. 8s. 6d. net.)

² *Nouveau Traité de Médecine*. Fascicule X. *Pathologie de l'Appareil circulatoire (Cœur et Vaisseaux)*. Tome I and II. *Cœur*. Publiée sous la direction de MM. G. H. Roger, Fernand Vidal, et P. J. Teissier. Paris: Masson et Cie. 1933. (Tome I: Pp. 992, 512 figures, 135 francs; Tome II: Pp. 778, 123 figures, 115 francs.)

details of the morbid anatomy of pulmonary and renal infarction. The conclusion is reached that excessive effort can strain a healthy heart. The chapters on shock, collapse, and syncope make interesting reading, though it is questionable whether such an elaborate classification of syncope is really helpful.

In the second volume, on diseases of the heart, further space is given to subacute endocarditis, no fewer than eleven types being distinguished. Coronary artery obstruction and infarction of the myocardium do not receive the attention they deserve, and there is no reference to the effects of thyrotoxicosis on the heart. Although there is in the two volumes a vast quantity of information, some of which it would be difficult to find elsewhere, it cannot be said that they will be of much value to English and American readers. The work suffers from the usual defects of similar French publications: there is no index; there are very few references; there is the customary disregard of other European and transatlantic authors. The type, however, is clear, and the paper of good quality.

"ROSE AND CARLESS"

Thirty-five years ago the first edition of Rose and Carless's well-known *Manual of Surgery*¹ was published, and since that time it has been the surgical guide of countless students the world over. There could be no better evidence that it still retains its popularity than the fact that a new (fourteenth) edition is called for but three years after the last. The editorship remains in the hands of Mr. C. P. G. WAKELEY and Mr. J. B. HUNTER, while the chapters upon "special" subjects are all sponsored by well-known exponents. The greatest change since the last issue is undoubtedly the production of the whole book on a surfaced paper, which has added to the clearness of the illustrations in general and, in particular, has enabled the radiograms to be placed in their proper position in the text, instead of being collected together in an appendix at the end of the book. Nothing can be more irritating than a frequent reference to illustrations out of their context, and we feel that this improvement alone enhances the value of the work considerably. The paper has been very carefully chosen, for, while allowing good reproductions of radiograms (notoriously difficult at all times), it is nevertheless not so surfaced as to render reading difficult on account of high lights. Three hundred new illustrations have been added in the text, and the plates brought up to twenty-four; nevertheless, the size of the book has not been increased.

On the purely technical side, a short but adequate description of the physics of radium is given, and also an account of the use of radium in the treatment of cancer of the various organs. The value of "sympathetic surgery" in the treatment of vasospastic and other conditions also receives notice, although in this regard we are surprised to see the statement retained that "thromboangiitis obliterans is a condition met with chiefly in Russian and Polish Jews who are heavy cigarette smokers." Buerger's original cases were perhaps of this type for geographical reasons, but the large number of cases now recorded in this country in non-smoking gentiles seems to prove that this disease has no racial restrictions. Böhler's methods of treating fractures are mentioned, and also the Winnett Orr treatment of infected bones. The newer methods of thoracic surgery receive attention, particularly in the case of empyema, and the student will derive sufficiently up-to-date information from this source regarding any treatment which

may be said to have received general acceptance and usage; it is obviously not the function of a student's textbook to deal with surgery in the experimental stage.

Although the constant change in surgical outlook renders it necessary to add fresh material in each edition, it is not primarily on account of its up-to-dateness that "Rose and Carless" has remained one of the most popular of all textbooks, but rather because of its sound teaching on general matters and the maintenance of a good balance. We are pleased, therefore, to note that the present editors have not altered the main characteristics of the work, so that it may still be regarded as one of the best general-textbooks on the subject, and one to which the student may turn with confidence.

PHYSICAL DIAGNOSIS OF DISEASES OF THE CHEST

The fifth edition of *Diseases of the Chest and the Principles of Physical Diagnosis*,² by G. W. NORRIS and H. R. M. LANDIS, has been published rather more than two years after its predecessor. New material has been added, including an account of the use of the bronchoscope in the diagnosis of respiratory affections. The physical methods of diagnosis in diseases of the chest are as important to-day as ever, and a comprehensive and detailed exposition such as this cannot fail to be of great service so long as it is kept well up to date. To this end revision has been undertaken at roughly two-yearly intervals, and some increase of size is inevitable. Illustrations in the form of photographs and diagrams have been used freely, and the pathological appearances are portrayed by clear reproductions of frozen sections. The book has a primarily practical outlook, and the various steps in conducting a complete examination of the heart and lungs are described in detail, every opportunity being taken to reinforce the verbal descriptions by photographs. Special attention is paid to the part played by acoustics in diagnosis; the origin of sounds heard, and the reasons for their transmission in certain directions and for their variation, are expounded at unusual length. The authors believe that such considerations are essential if full value is to be gained from percussion and auscultation. The normal findings are given in each case, and the explanation of the changes induced by different anatomical and pathological modifications is set out at length. The authors have achieved their expressed purpose of compiling a book which shall indicate how very large a part must be played in diagnosis by careful and instructed physical examination.

HISTOPATHOLOGY OF THE UTERINE MUCOSA

The histopathology of the uterine mucosa presents peculiar difficulties, partly because of the normal cyclical variations which occur in it, and partly because so much of the material which reaches the laboratory is damaged by the curette. Professor DEELMAN had the happy inspiration to provide a book to aid the gynaecologist and the pathologist in the study of this difficult terrain.³ It contains 248 illustrations, most of them photomicrographs, and the standard magnifications depicted are 10-15 and 100-180. The book, of 247 pages, is divided into eight sections, dealing respectively with the endometrium of pregnancy and its pathological changes, hydatidiform mole and chorion epithelioma, endometritis, atypical sections,

² *Diseases of the Chest and the Principles of Physical Diagnosis*. By G. W. Norris, A.B., M.D., and H. R. M. Landis, A.B., M.D., Sc.D. Fifth edition. London: W. B. Saunders Company. 1931. (Pp. 897. 50s.)

³ *Die Histopathologie der Uterus-mucosa*. Von Dr. H. T. Deelman. Leipzig: G. Thieme. 1933. (Pp. 247; 248 figures. M.22; Geb. M.24.)

uterine polypi and other benign growths, carcinoma of the uterus, hypertrophy and glandular hyperplasia of the endometrium, and the pathology of the endometrium during the climacteric. The author has tried not to advance any original views, but to illustrate and describe pathological conditions which he has met with in the vast amount of material he has handled during the last ten years. Most writers of textbooks illustrate any given pathological condition with pictures from a typical section, and it is the common experience of the student looking down the microscope that typical sections are rarely encountered. Professor Deelman has attempted to provide as many different pictures of each condition as possible, and has not hesitated to include photomicrographs of sections from which he was only able to make an alternative diagnosis. It is encouraging to realize that such an authority is unable in some cases to decide between carcinoma and chronic inflammation. The illustrations are good, and for the most part depict what the author describes—and he is economical in the use of words.

Professor Deelman is to be congratulated, not only on adequately accomplishing a difficult task, but on initiating a new type of book. We know of none other that possesses anything approaching the same value to the gynaecologist desirous of studying the histology and the pathology of the uterine mucosa.

Notes on Books

Calcium Metabolism and Calcium Therapy,* by Dr. A. CANTAROW, first appeared in 1931, and a second edition has now been published. The fact that this has been required so soon indicates that the monograph has been found very useful by the medical profession. A full account of existing knowledge about calcium metabolism and therapy was given in the first edition, and in consequence the author has not now found it necessary to make any extensive changes. Calcium metabolism presents many problems of peculiar difficulty, and our knowledge on many points of fundamental importance is still very incomplete. The amount of research in this subject is considerable, and steady progress is being made, but no very striking advances have been recorded. A perusal of the volume shows that the author has included a full account of all the more important work that has been published since the appearance of the first edition. It gives as clear and concise a presentation as is possible of a difficult subject, and can therefore be recommended.

The fifty-third volume of *The Transactions of the Edinburgh Obstetrical Society*† comprises the work of the session 1932-3, and opens with the presidential address to the society delivered by Dr. James Young in November, 1932, the subject being the medical schools and the nation's health. The obstetrical contributions deal with the x-ray diagnosis of placenta praevia, delayed labour due to haemangio-lymphangioma of the foetal neck, recent views on the physiology of the gravid uterus, bilateral cortical necrosis of the kidneys occurring during pregnancy, the sodium morrhuate treatment of varicose veins in pregnancy, and a review of the maternity mortality problem, with special reference to the work of William Smellie. Gynaecological articles relate to the application of radiotherapy in gynaecology, risks attached to uterine curetting, post-menopausal haemorrhage, oestrin in the treatment of functional secondary amenorrhoea, pruritus vulvae treated by A.B.A. (a mixture of amido-benzoic acid-ethyl-ester, benzyl alcohol, and ether in an oily medium), and neuritis of the broad ligament. An index is supplied, and the volume is illustrated by photographs,

Dr. LOGAN CLENDENING's book, entitled *Behind the Doctor*,* is a popular work on the history of medicine, containing in narrative form an account of the most important discoveries in physiology and medicine. Though primarily intended for the layman, the book will provide attractive reading to practitioners who are not specially interested in medical history. The text is liberally interspersed with portraits and other illustrations.

The fourth edition of *Nursing Homes*† includes a special section devoted to establishments undertaking the care of tuberculosis patients. Another feature, and one which should increase the usefulness of this yearbook to the medical profession, is the indication by means of an asterisk of those nursing homes which are prepared to supply nurses for outside work. The directory, which forms the main portion of the volume, contains details of nearly 3,000 registered nursing homes.

The story of the medical missions of the London Missionary Society has been told in a little illustrated book entitled *The Doctor Abroad*‡ by ERNEST H. JEFFS. The author's aim is to awaken, or to confirm, in those who read his pages, admiration for the men and women pursuing that vocation. We may take this opportunity to mention also a publication of the Church Missionary Society, in its Africa and the East Series, entitled *Hospitals Overseas*§.

* *Behind the Doctor*. By Logan Clendening, M.D. London: William Heinemann (Medical Books) Ltd. 1933. (Pp. xxi + 458; 147 figures. 2s. net.)

† *Nursing Homes*, 1934. London: Benn Bros., Ltd. (Pp. 22, 3s. 6d.)

‡ *The Doctor Abroad*. By E. H. Jeffs. London: The Livingstone Press. 1934. (Pp. 89. 1s.)

Preparations and Appliances

HOOK FOR REMOVAL OF PROSTATIC FRAGMENTS AFTER ELECTROTOME RESECTION

Mr. F. MCG. LOUGHNANE, F.R.C.S. (London, W.), writes: In the operation of prostatic resection with the McCarthy visual prostatic electrotome it often happens that one or more pieces fail to come away when the loop and telescope are withdrawn from the sheath. Failure may be due to the fact that: (1) the piece resected is too large to engage easily in the sheath; (2) the inflow instead of the outflow tap may be open at the time, thus allowing the piece to be washed back into the bladder; (3) the loop may be operated too quickly, thus minimizing coagulation and adherence of the piece to the loop.

Sometimes with repeated irrigation some of the retained pieces may wash out, but often one or two fail to do so. If these pieces are left behind complications may ensue. These are: (1) sepsis, or aggravated cystitis; (2) blocking of the indwelling catheter with retention, and, if there is bleeding, clot formation; (3) pain and strangury if the piece is passed naturally along the urethra, or retention if the piece becomes impacted.

It is thus readily understood how necessary it is to be certain that no pieces have been left behind in the bladder at the end of the operation. Pieces can, of course, be removed with forceps through an operating cystoscope, but this entails the use of another instrument, and the method is not always simple or easy.

To effect easy and rapid removal of retained pieces I have devised a hook, as illustrated. It is made of steel, and has two terminal bent prongs. The shaft is the size and shape of that of the loop. To use it the loop is removed and replaced by the hook. The hook is operated by the rack and pinion, and the loose pieces, easily located, are raked back into the sheath and withdrawn. It is advisable to inflow two or three ounces of fluid into the bladder before operating, and care must be taken not to catch the points of the hook in the bladder mucosa. If this happens advancing the hook will release it.

I have to thank Mr. Schranz of the Genito-Urinary Manufacturing Company, Ltd., for the manufacture of instrument.

Therapy. By A. Cantarow, H. Kimpton 1933. (Pp. 252. 12s. 6d. net.)

† *Transactions of the Edinburgh Obstetrical Society*. 1932-3. Vol. III. Edinburgh: Oliver and Boyd. 1933. (Pp. 176.)

THE SERUM TREATMENT OF LOBAR PNEUMONIA

A REPORT OF THE THERAPEUTIC TRIALS COMMITTEE OF THE MEDICAL RESEARCH COUNCIL

During the last three years the Medical Research Council have assisted an inquiry at different centres in Great Britain into the therapeutic value of specific sera for lobar pneumonia, following the great development of similar work in the United States. When the Council appointed a standing Therapeutic Trials Committee in 1931 the investigation was placed under the control of that committee, and the present report summarizes the evidence obtained.

The work has been laborious; for it was little more than a critical testing for practical use of methods which were already in common knowledge, and it involved the close consideration of a very large number of cases of pneumonia. The Council wish to express their gratitude to the workers who so willingly undertook this prolonged study, and brought their results together for joint consideration.

Interest in the treatment of pneumonia has for many years been felt more keenly in Scotland, where the disease is perhaps more prevalent in the winter months, than in England. For evidence used in the present report the committee are indebted to workers in Aberdeen, Edinburgh, Glasgow, and London. The observations at Edinburgh were made by Professor D. Murray Lyon and the other physicians to the Royal Infirmary; those at Aberdeen by Professor Stanley Davidson, Dr. J. B. Ewen, and Dr. R. J. Duthie, in the City Hospital, Woodend; and those in London by Dr. R. R. Armstrong and Dr. R. Sleigh Johnson in various London County Council hospitals and also at St. Bartholomew's Hospital. The Glasgow inquiry under Dr. John Cowan, Dr. A. W. Harrington, and Dr. R. Cruickshank was developed independently with support from the Scottish branch of the British Red Cross Society, but permission has kindly been given for the use of their results. Separate reports have been, or will be, published independently by these various workers. The present summary expresses opinions agreed upon at all four centres. The practical conclusions are based directly on the evidence obtained there, but it will be evident to anyone familiar with American work that they are not widely dissimilar from those accepted in New York and Boston.

During the two winter seasons 1931-2 and 1932-3 a total of 773 cases of lobar pneumonia between the ages of 20 and 60 years were studied at Aberdeen, Edinburgh, and London. Of these, 530 belonged to either Type I or Type II, and 241 were treated by serum. The figures for Glasgow for 1930-3 were 602 cases from 20 to 60 years old, of which 434 belonged to Type I or II, and 107 were treated by serum. It will be noted from what follows that a large series of cases is required in order to demonstrate fairly any beneficial action of the serum.

Typing of the Pneumococcus

This was generally done on the fresh sputum, selecting that which was of a glairy (rusty) "pneumococcal" appearance rather than purulent expectoration. Lung puncture was rarely used. Sputum up to twenty-four hours old may be employed, but it is less satisfactory and was never employed in the present series.

The rapid method recommended by Armstrong of immediate typing from the sputum itself on a microscope slide was employed tentatively. This offers great advantages, not only in speed, the test requiring less than half an hour, but still more in that it can be used in places which are not licensed for experiments on animals. But it may be unsatisfactory with the horse sera that are usually provided for type testing, and most workers are

agreed that a clear result under the microscope is more often obtained when rabbit sera are employed. The Glasgow observers, however, have compared the results with concentrated horse serum and with rabbit serum, and conclude that these are equally reliable, provided that the serum, whether of horse or rabbit, has an agglutinin titre of, say, 1 in 160 to 1 in 320.

In every instance in the present series, excepting a few of Dr. Armstrong's group, the final typing was recorded on the result of animal tests, Sabin's method of examining the peritoneal exudate four hours after inoculation into mice being generally used, and if that failed the examination being completed later when the mouse was dead or moribund. Whatever the method used, some special experience is required for accurate results, and it should be ascertained that the diagnostic sera are reliable. More than one specimen of sputum should be examined to confirm the type.

Serum Used

The therapeutic antisera were those made for the market either by the Lederle Antitoxin Laboratories, or Messrs. Parke, Davis and Co., or Messrs. Burroughs Wellcome and Co. The Council and the investigators are indebted to these firms for special facilities given in the supply of the sera. Almost all the observations were made with concentrated serum, the power of which to protect mice had been measured in the American Felton units.

It is clearly desirable that any further evidence as to the value of anti-pneumococcal sera shall be based on dosage expressed in stable and generally accepted units. During the progress of this investigation, action to facilitate such uniformity of notation in this country has been taken by the Standards Department of the National Institute for Medical Research. Suitable anti-pneumococcal sera of both Types I and II have been dried and are preserved under conditions ensuring permanence, the value of each having been measured in terms of the Felton unit, unofficially current in the U.S.A., by comparison with samples supplied for this purpose by Dr. Felton himself. Of these provisional British standards, that for Type I serum has for some time been on regular issue to the manufacturers of anti-pneumococcal sera for sale in this country, and a similar distribution of the Type II standard will shortly follow. Pending an international decision, and subsequent official action, this voluntary distribution should ensure that data relating to the dosage of anti-pneumococcal sera from different sources should be strictly comparable both here and in America, where a similar voluntary adoption of the Felton units is effective.

The serum has been given intravenously in all the cases under review. Intramuscular injection was found by some workers to cause painful swelling, and has the theoretical disadvantage that the antibodies may not be absorbed into the circulation as quickly as is desirable.

The beneficial action of serum, which is so conclusively evident in mice, is believed to be sharply specific for each type of pneumococcal infection. American evidence on this point was accepted, and accordingly no attempt was made in this inquiry to learn whether the benefit produced in the human patient might not be equally well obtained by treatment with simple horse serum or with a non-specific type of antiserum.

The treatment with serum was begun as early as possible, though in some instances the patients were first allowed several hours' rest in hospital to recover from the exhaustion caused by transport. If the infecting pneumococcus could be typed without many hours' delay no serum was given until the answer enabled treatment to be started at once with the appropriate antiserum. Otherwise a preliminary dose of 20,000 units of Type I, together with 20,000 units of Type II, was given; and subsequent treatment adjusted to the proper serum or abandoned in accordance with the type of pneumococcus ultimately found. The routine injection of the single specific serum was usually 20,000 units repeated about every eight hours or at least twice in a day. If the patient showed no clinical improvement after forty-eight

hours' treatment with serum, it was generally found to be useless to continue with it. But some severe cases which were beginning to improve but had not yet reached safety received more prolonged treatment. The total dosage of serum varied from 50,000 to 120,000 units in different cases; Type II cases seemed on the whole to require a larger dosage than Type I. After the fifth day of the illness it was generally felt, though not proved, that serum had no further useful action.

Very few instances of immediately harmful reaction to the serum were ever observed either at Glasgow or at Aberdeen. When these occurred they took the form of slight dyspnoea with tachycardia; the dyspnoea was immediately relieved by adrenaline. In both winter seasons there were at Edinburgh and in London several instances of alarming, though not fatal, reactions to the first injection of a few batches of a mixed I and II serum. These ill-effects were rigors, or dyspnoea and increasing cyanosis, or general collapse with a feeble pulse. Such reactions were considered to be "toxic" rather than "anaphylactic," for they were seen in several patients treated with a particular batch of serum, rather than in an occasional sensitive individual; they were worse the larger the amount of serum injected, and they were not alleviated by adrenaline. When a particular batch of serum was once known to be clinically "safe," it could be used on any patient with no further precaution than that of slow injection into the vein.

Delayed serum reactions were rare and slight with the concentrated sera. During the recent winter Dr. Armstrong, in London, used an unconcentrated "Wellcome" serum of high titre, which was one-third less costly. This unconcentrated serum was also tried to a small extent at Glasgow. Neither it nor the concentrated "Wellcome" serum ever caused severe immediate reactions, but the use of the unconcentrated product was more frequently followed by late effects such as rashes, swollen joints, and pyrexia. The unconcentrated serum appeared to be as effective as the concentrated form in controlling the pneumonia, provided that the same number of Felton units were given.

Taking the market price of the concentrated serum as 30s. for a phial of 20,000 units, the treatment of an ordinary case of lobar pneumonia with 80,000 units would cost £6.

Selection of Cases for Treatment

The good results of insulin on patients with diabetes or of liver treatment in pernicious anaemia are so constant that the trial of these remedies in a very few cases was enough to establish their value. With the antiserum treatment of lobar pneumonia the conditions are very different. The action of the serum is only that of a partial factor for good, and its influence may be overwhelmed by an infection that has been allowed several days to establish its dominance in the patient, or by other complicating factors that weaken the patient's resistance. In order to measure precisely what this partial benefit may be it would be necessary to take two groups of cases of identical severity and initial history and compare the sickness and the fatality in each, the one being treated with serum and the other serving as a control. But this is impracticable, for few cases, even of "Type I" lobar pneumonia, are quite alike, and a sufficient number of similar cases could never be got together under one observer and under similar conditions. Some American workers have sought to avoid this difficulty by using a special system of ratings for the various harmful features of the disease, thus expressing each patient's numerical value in reference to a common standard. Such differentiation seemed too intricate, and perhaps too much a matter of personal judgement, for the present inquiry. If a straightforward comparison of treated cases with controls, under the average conditions whereby patients succeed one another in the wards of a hospital, could not reveal any advantage for those treated by serum, then common sense would conclude that the use of this remedy should be disregarded in the routine

of practical medicine. The method consequently agreed upon for London, Edinburgh, and Aberdeen was that alternate cases of lobar pneumonia; taken simply in the order of their admission to hospital, should be used respectively for serum treatment and controls. So far as possible both were treated in the same wards and under the care of the same physicians. In the independent inquiry at Glasgow, however, the "serum" cases were treated in the Royal Infirmary, and a series of patients of the same social stratum, admitted during the same period to the Belvidere Isolation Hospital under the care of one physician, served as the control group. It is clear that there may be serious fallacies in any system which contrasts a group of serum-treated patients with a control group drawn from a different stratum of the population, or with a control group in a previous year, when the severity of the prevailing pneumonia might have been different.

Certain principles of selection were laid down so as to make the data derived from the centres homogeneous, and to exclude from the comparison patients in whom the serum could not be expected to have any effect. For the latter reason all patients admitted later than the fifth day of illness were excluded from the inquiry. Also all patients dying within twenty-four hours of admission to hospital were then taken out of the series, though the evident severity of their illness would not have prevented their inclusion at first, either in the control or in the serum group. No case of pneumonia complicated by other obvious disease, such as gross nephritis, advanced heart disease, diabetes, etc., was accepted for either group. All forms diagnosed as bronchopneumonia were also excluded. That these limitations were desirable was agreed upon by all the workers at a preliminary conference on the subject. It will be appreciated, however, that, with such restrictions, it was difficult in three years to obtain fully adequate data for statistical purposes; thus, to take the Aberdeen figures as an example, 450 patients with pneumonia were admitted to the City Hospital, Woodend, during the period under review, but with the agreed limitations the number was reduced to 188, of which seventy were Type I cases, giving a total of only thirty-five available for treatment with Type I serum.

Sex was disregarded, but the question of age was too important to be neglected. Table II from the present series illustrates afresh the well-known fact that the fatality of lobar pneumonia tends to be much greater over the age of 40 than in younger persons. The fortuitous inclusion of a few more elderly patients in one group than in the other might influence unfairly the final figures for comparison. It was therefore decided to omit from the series all patients under the age of 20 and over the age of 60, and to classify the remainder into broad age groups. It will be noted that this plan still left altogether unregulated the chance scatter of distribution of patients with severe or mild pneumonia into either the serum or control groups, and also of those admitted for treatment early or relatively late in the progress of the disease. It was thought better not to attempt a deliberate sorting of cases in respect of mildness or severity, but to trust that the distortion of chance scatter would become almost negligible in a fairly large number of cases. Reference to a possible influence of the "severity factor" on the results is, however, made later in the report.

Statistics of Results

Subject to the criteria mentioned above, patients at London and Aberdeen were placed in the groups for serum treatment, or for control, alternately in the order of their admission to hospital without selection as to age or severity. At Edinburgh the same general rules and criteria were observed, and there was no selection of cases for serum treatment. But in some wards of the Royal Infirmary serum was not used throughout the whole period of the inquiry, and consequently the patients from these wards overload the number of controls. In the other wards the alternate case plan was maintained to the end. At Glasgow the alternate case plan was not

used, but patients in one hospital were treated with serum and those in another hospital served as controls. Hence it is only at Aberdeen and London that the serum-treated cases equal the control cases in number.

TABLE I.—Type Incidence in Lobar Pneumonia for Cases of the Special Series

	1931-2	1932-3	Totals
Aberdeen:	per cent.	per cent.	per cent.
Type I ...	26 = 29.2	44 = 44.4	70 = 37.0

* In this table the data from Edinburgh, though not from the other centres, include patients dying within twenty-four hours of admission to hospital; hence there are two more Type I and eight more Type II cases in this table than in Table III.

The variability of the type incidence from season to season and from place to place shows how epidemics of pneumonia may differ bacteriologically, but, on the basis of these and other published figures, it may be assumed that two-thirds of all cases of lobar pneumonia in Great Britain belong to types which are suitable for treatment by the sera now available.

That the fatality of lobar pneumonia is influenced by the type of infecting pneumococcus as well as by the age of the patient is confirmed by the following table for the Type I and Type II cases from the present series.

TABLE II.—Fatality in Different Age Groups for Cases Treated Without Serum

Totals for Aberdeen, Edinburgh, Glasgow, and London

	Ages: 20-60			20-30			30-40			40-50			50-60

* The "expected deaths" are those which would have been recorded if the serum-treated groups had died at the same percentage rates as the corresponding controls.

From the combined figures from the four centres it would appear that serum treatment is capable of reducing the fatality from Type I and Type II pneumonia, but that the improvement is limited to patients under the age of 40. It is unfortunate, from the point of view of statistical analysis, that the number of patients over the age of 40 who were available for treatment was so much smaller than the number of younger patients. Nevertheless, on this evidence, it would seem that the life-saving effects of serum treatment are mainly, if not wholly, restricted to the ages at which natural resistance to the disease is ordinarily high. Looked at broadly the results do show a favourable influence on the fatality rate in the younger patients with Type I and also with Type II antisera. But a closer inspection of the separate results from each centre reveals anomalies that demand further analysis.

Aberdeen showed a fatality rate in Type I pneumonia which was reduced with serum from the expected figure of six to only one in thirty-five cases. London, on the other hand, found the fatality rate in Type I slightly increased with serum, whereas that in Type II was reduced to four from the expected figure of ten deaths. The aggregate London figures are the more surprising, because Dr. Armstrong himself had in his first winter's experience been vividly impressed by the benefit obtained with serum in Type I cases, and it was contrary to all his expectations when the figures of the second year swung the balance away in the opposite direction. In commenting on the change he observed that eighteen of his treated Type I cases were clinically classified as "severe," compared with only seven "severe" cases among his controls. This raised the question of the chance scatter of patients with poorer prognosis from any cause into either the serum or the control group preponderantly. But the case records at the other centres were carefully revised from this point of view, and there was no evidence of the control groups having been unduly weighted by the chance occurrence of severe cases among them.

Apart from clinical judgement, the severity of an individual case may be estimated by the results of blood culture and by measuring the leucocytosis. The latter method was used in routine examination at Aberdeen and Glasgow, though not at the other two centres. An initial leucocytosis below 15,000 per c.mm. carries a relatively unfavourable prognosis. Examination of the records from Aberdeen shows that on the whole the initial leucocyte counts were higher in the cases which happened to be treated with serum than in the controls, but there was no great inequality in this respect. Nor was the explanation to be found in an unequal incidence of early bacteraemia. Table V indicates that there were as many cases of early bacteraemia in the serum as in the control groups. The variation in the results at the different centres cannot be explained, but they show the difficulties in the way of accurately evaluating a treatment of this nature on the basis of small numbers of cases.

Bacteraemia

At Aberdeen blood cultures were systematically taken throughout the inquiry; they were made on every patient and early after admission, but only once. Positive blood cultures were obtained in nineteen out of sixty-six consecutive cases (28.8 per cent.) by the method finally adopted of withdrawing blood by a syringe and injecting it directly into glucose broth. The earlier technique of using citrated blood in "venule" tubes for transference to broth gave a lower proportion of positive results. At Glasgow blood cultures were taken from all but twelve of the serum cases, and from 138 consecutive controls between the ages of 20 and 60; the cultures were made as soon as possible after admission, and the method of directly injecting the blood into glucose broth was adopted throughout. Table IV gives the total figures submitted from these two centres without distinction between the early and later methods of culture used at Aberdeen.

It would appear from the results shown in the table that serum treatment has little influence on the total fatality rates of cases with bacteraemia.

TABLE IV.—Incidence of Bacteraemia in Type I and Type II Cases (Serum and Controls) at Aberdeen and Glasgow

Type	Serum					Controls				
	Cases Examined	Positive	Deaths	Negative	Deaths	Cases Examined	Positive	Deaths	Negative	Deaths
I	61	28	5 (17.9% of positive cases)	56	0	95	23	4 (17.4% of positive cases)	72	11
II	65	18	7 (38.9% of positive cases)	47	7	93	22	11 (50% of positive cases)	73	8

Effect of Serum Treatment on Duration of Illness in the Surviving Cases

Here, if anywhere, it should be possible to show clearly the favourable action of antiserum. In a series of one hundred patients there may be twenty so heavily infected that they would normally die, and only a few of these twenty are in a state where reprieve from death is possible by the use of serum. The eighty potential survivors must all be patients with less severe infection: they are mostly well inside the zone at the edge of which serum could just show its efficiency by saving a few cases from death. It is helpful to visualize this by a rectangular diagram in which a black area shows the 20 per cent. of massive and fatal infection, while the remaining 80 per cent. of progressively lighter tint includes all those in whom the infection was below the intensity needed to kill. Antiserum may push the black band a little further back, to 15 per cent. or less, and then it meets a final barrier. But through all the great area of survival cases it should also be effective in lightening the grey tint of illness.

There has been too little attention given to the action of serum on surviving cases. This is partly because it is less easy to make an exact analysis of such clinical improvement than to record the simple fact of death or survival; and partly because physicians are chiefly concerned with the hope of saving the life of a patient with pneumonia, knowing that if only this can be achieved convalescence is usually rapid, whether the pneumonia had been severe or mild. But the survivors offer for study a field where the effect of the serum should be more easily demonstrable, since they are presumably in that state of relatively light infection where the serum can act to full advantage.

At all four centres the experience was alike—namely, that the serum treatment of Type I and also of Type II cases lessened the duration of the fever and diminished the number of cases in which fever ended irregularly by lysis.

Aberdeen reported:

Type I pneumonia; average time of crisis:

In serum-treated cases, 33.8 hours after admission to hospital.

In control cases, 101 hours after admission to hospital.

Type II pneumonia; average time of crisis:

In serum-treated cases, 36.6 hours after admission to hospital.

In control cases, 104 hours after admission to hospital.

Edinburgh and Glasgow used a different measure for the recovery, but the improvement was equally evident. The percentages of cases in which the fever ended on or before the fifth day of the disease, disregarding time of admission to hospital, were:

Edinburgh:

Type I pneumonia: serum-treated, 36.4 per cent.; control, 8.3 per cent.

Type II pneumonia: serum-treated, 34.2 per cent.; control, 10.9 per cent.

Glasgow:

Type I pneumonia: serum-treated, 72.1 per cent.; control, 9.5 per cent.

Type II pneumonia: serum-treated, 34.1 per cent.; control, 5.3 per cent.

Dr. Armstrong in London found that the time of crisis occurred on the average two and a half days earlier in the illness in his serum-treated Type I cases, and two days earlier in his serum-treated Type II cases, than in the controls. The Glasgow workers also found that the average times of crisis in the serum-treated Type I and Type II cases were respectively two and a half and two days earlier than in the corresponding controls. Dr. Armstrong's table may be quoted in full, because it illustrates this clinical improvement in the survivors, despite a failure to influence the death rate in Type I cases (Table V).

TABLE V.—Effect of Serum Treatment on the Course of the Illness in Survivors (London)

	Type I				Type II			
	Treated		Control		Treated		Control	
	Cases	Av. day	Cases	Av. day	Cases	Av. day	Cases	Av. day
Crisis	47	4½	35	7½	25	4½	19	6½
Lysis	12	7	26	9½	7	7½	11	9½
Continued fever ...	2	—	1	—	0	—	0	—

Data with regard to the convalescence were generally unreliable, because most of the patients were granted a routine time for recovery, and often a holiday before they were advised to resume full work.

In view of its effect on the course of the illness in Type I and Type II pneumonia, it might be expected that serum treatment would lessen the incidence of complications in patients who recovered from the initial infection. The total numbers of individual complications in both the serum-treated and the control groups at the four centres were, however, too small to enable fair comparisons to be made, except in the case of the important local complication empyema. There was a suggestion from the total figures that the liability to this complication was reduced by serum treatment in both Type I and Type II pneumonia. The figures submitted from the four centres showed that empyema occurred in four serum-treated Type I cases, against an "expected" figure of nine, and in one serum-treated Type II case, against an "expected" figure of three; in each case the expected figure was calculated from the incidence of empyema in the corresponding control group. The percentage incidence of this complication in the serum-treated and control groups for Type I and Type II pneumonia was as follows:

Type I: serum-treated, 2.4 (166 cases); control, 5.5 (236 cases).
Type II: serum-treated, 0.8 (131 cases); control, 2.7 (223 cases).

The evidence of the inquiry at the four centres is therefore in favour of the serum treatment, although with certain limitations. The inconveniences to the patient are little more than those of repeated intravenous injections. Fatality was reduced in the younger patients in this series by roughly half of the expected deaths. Thus in 140 serum-treated cases, aged 20 to 40, of Type I pneumonia there were eight deaths instead of the expected sixteen; and in 111 serum-treated cases of Type II there were fourteen deaths instead of the expected twenty-five. Also, the duration of illness among survivors tended to be shortened by from two to three days, curtailing just that period near the end of a pneumonia where anxiety grows as the fever persists; and was a suggestion that the incidence of empyema was lessened by giving serum. These benefits were obtained with both Type I and Type II cases of lobar pneumonia. On the other hand, the data obtained in this investigation suggest that serum treatment has little or no power to decrease the fatality from Type I or Type II lobar pneumonia in patients over 40, or in the severely ill cases with bacteraemia.

On clinical impressions the workers were all agreed that the appropriate antiserum frequently produces striking symptomatic benefit in cases of Type I and Type II lobar pneumonia, and that the best results are obtained with very early treatment. There was a con-

sensus of opinion at the four centres that it is probably useless to give serum later than the fifth day of the disease.

Summary

1. Concentrated antiserum for Type I pneumococcus reduced the fatality in Type I cases of lobar pneumonia in adults between the ages of 20 and 40; from the total figures of the present inquiry, however, the treatment appeared to have little, if any, effect on the fatality in older patients (aged 40 to 60). The treatment seemed definitely to reduce the average duration of fever and illness in patients who recovered, and there was a suggestion that it also decreased the liability to empyema among survivors.

2. Similar effects were seen when Type II antiserum was used for cases of Type II lobar pneumonia.

3. Immediate serum reactions of a dangerous nature were rarely seen in the present series of cases, except that one or two batches of a particular concentrated mixed serum did cause rigors and collapse at both the centres where they were used. There were no unpleasant late anaphylactic results with the concentrated serum. On the whole, a good serum seemed to be devoid of disturbing effects on the patient, and on these grounds there need be no hesitation in the use of the treatment.

4. The benefits from serum are not so emphatic as to make it desirable that all severe cases of lobar pneumonia, irrespective of the type of the infecting pneumococcus, should be treated with Type I and Type II antiserum on the chance that they might belong to a type which is favourably influenced. Moreover, the special technique required for repeated intravenous injections, and the cost of the serum, make the treatment unsuitable for universal application. Each case must be typed as soon as possible, so that the appropriate serum may be used in the optimum dose; the use of the serum is not recommended except under conditions where typing of the pneumococcus can be obtained.

5. If accurate typing of the sputum can be done in five or six hours, serum should be withheld until the type is known, and then a dose of 20,000 Felton units of the specific serum given. But if more time is required for the typing, then a preliminary dose of 20,000 Felton units Type I, together with 20,000 units Type II, should be given, and the specific type serum, either I or II alone, continued when the nature of the infection is known. Treatment is continued by injection of 20,000 units at a time, twice a day, with approximately an eight-hour interval. Usually a total dosage of 80,000 units, with variation from 50,000 to 120,000 units, of the single specific serum is required, Type II cases, on the whole, needing a larger dosage than Type I. If no obvious clinical improvement occurs in the first forty-eight hours of serum treatment it is probably useless to continue with it.

6. The serum should be given intravenously. There is no satisfactory preliminary test for any peculiar sensitiveness of the patient to horse serum. The first injection should therefore be made cautiously and slowly, 1 c.cm. being introduced into the vein in a minute or two, and the total being injected in ten or fifteen minutes. Adrenaline solution 1 in 1,000 must be ready beforehand, and 1/2 or 1 c.cm. of this should at once be injected subcutaneously if the patient reacts unfavourably with collapse and failure of the pulse or urgent dyspnoea. Second and subsequent injections of serum may be given with less precaution. In addition to anaphylactic sensitiveness of the individual, there is the chance that the serum supplied by the manufacturer may contain protein substances which are toxic to most individuals, as occurred in a few batches used in the present inquiry. To safeguard against this, 1 c.cm. of the serum may be injected intravenously, and the remainder of the dose slowly injected half an hour later, provided that no untoward symptoms have occurred. This precaution is unnecessary if the batch of serum is known to be harmless, either from other experience or because the manufacturers state that it has already been tested from this point of view.

7. No data were collected in this inquiry with regard to the use of the serum in children, or in patients over the age of 60, or in cases of bronchopneumonia.

DIET AND THE TEETH

The investigations into the influence of diet on the teeth which Mrs. Mellanby has prosecuted during the past sixteen years are well known, and indeed have already modified profoundly our conceptions regarding the causation of dental caries. The first full report on this work, published in 1929 (Medical Research Council, Special Report Series No. 140), dealt with the effect of diet on the development of the jaws and the teeth of young dogs. In this the author showed that lack of vitamin D caused defective formation of the teeth and jaw bones, while lack of vitamin A paved the way for infection of the alveoli of the teeth and produced a condition resembling pyorrhoea alveolaris. The second report (No. 153 of the same series, 1930) traced the influence of diet on the teeth of mammals other than the dog. A brief interim report appeared three years ago (No. 159, 1931) on the influence of diet on caries in children's teeth. Mrs. Mellanby has also published a number of shorter communications on the results of her work.

A full report on the influence of diet on dental structure and disease in children has now appeared,¹ and this publication completes Mrs. Mellanby's account of her long-continued researches. Dental caries is the commonest permanent disability that affects our population, and this document has naturally aroused wide interest, not only in the medical profession, but also among the general public. The argument therein set out rests on three main theses. In the first place, the author demonstrates that the average tooth is a poorly developed structure, highly susceptible to decay, but that greatly improved development can be brought about by a better choice of food. Secondly, experimental evidence is presented showing that the incidence and progress of dental caries in children can be checked or even arrested by suitable modification of the diet. Thirdly, the author shows that dental caries is most capricious in the extent to which it afflicts communities, that certain populations are nearly free from this disease, and that freedom of communities from caries is correlated with special dietary habits. The experimental work indicates that the diet most effective for ensuring normal tooth development and freedom from caries is one rich in fat-soluble vitamins and with a low cereal content. A diet of this type is found in certain fishing communities who live chiefly on fish and potatoes. Dental caries is therefore regarded as a deficiency disease that can be checked by special dietary precautions. Mrs. Mellanby has shown that the teeth need for their formation adequate supplies of calcium

and phosphorus, and an ample supply of vitamin D to ensure that these are put to proper use. Her studies of the nutritional factors that control the laying down of secondary dentine indicate that these same factors are necessary for the teeth throughout life, and especially for the recuperative process of which all teeth are capable and upon which the arrest of dental caries depends.

These findings are of great sociological importance, and the work will very properly be subjected to close scrutiny and criticism. In order to get the matter into perspective we must bear in mind the scope of the inquiries upon which the conclusions rest. The work on animals and children has been prosecuted continuously for sixteen years, and the conclusions regarding human teeth are based on histological examination of sections of some 2,000 teeth amplified by careful inspection *in situ* of some 30,000 teeth. The dietary experiments involved a total of over 400 children, and had an average duration of about two years. These researches are therefore on a scale quite unusual both in extent and in duration. From one point of view this is a disadvantage, because, since it requires several years of highly specialized and laborious research to produce evidence of any value in this field, it will therefore take a long time for independent confirmation or disproof of these important conclusions to be obtained. Put very briefly, the general lesson that emerges from Mrs. Mellanby's work appears to be that a civilized community can have good teeth at a price, but that the price is a thoroughgoing change in ordinary dietary habits. The regular administration of cod-liver oil will effect a considerable improvement in the dentition of children, but in order to ensure perfect dentition we must also cut down the cereal intake, for cereals she regards as the most powerful ally of caries. Their tendency, judged by the outcome of her experiments in Sheffield and Birmingham, is to neutralize the action of vitamin D, essential to the proper metabolism of calcium and phosphorus.

This report deals with studies commenced in 1917, and during the past ten years Mrs. Mellanby's work has attracted general attention and has already brought about a change of attitude towards the causation of dental decay. This, then, is an opportune moment to note the fundamental importance of her inquiries. When they began, caries was regarded as a simple problem of bacterial invasion which could be combated only by oral hygiene, while the tooth was assumed to play a passive part in the process. Mrs. Mellanby's work has provided the conception of teeth as living organs which can resist decay if their development and structure are normal. This new view has gradually gained acceptance in the last decade, and to-day there is some danger of forgetting how great has been the change in outlook caused by the researches under review. Even if some may think that she makes by inference too little of the factor of oral hygiene, we must all congratulate Mrs. Mellanby on the rounding off of a remarkable piece of work in experimental therapeutics.

FORTY YEARS IN PUBLIC HEALTH

The retirement this month of Sir George Seaton Buchanan from the Ministry of Health, at which, and at the Local Government Board before its creation, he has served in the medical department for nearly forty years, cannot pass unnoticed. In public health he, like his father (Sir George Buchanan, F.R.S.), who was medical officer of the central health department before him, has represented during all these years the type of effective and unobtrusive work for the community which is done by our Civil Service when at its best. His record has been one of great variety. It began, as can be seen by anyone who consults the reports of the Local Government Board from 1895 onwards, with work over the whole range of public health as understood at the end of last century: field studies of infectious disease outbreaks; water supply and sewage disposal questions; housing—a report by him on the Border town of Alnwick in 1898 was a notable pioneer effort at slum clearance—and many other subjects which have now become so specialized that their medical element is almost submerged and the original medical initiative forgotten. Always ready to seize opportunities for administrative reform, Buchanan took advantage of the public demand for a new Government outlook on food supplies and health occasioned by the outbreak of arsenical poisoning from beer in the Midlands and Lancashire in 1900, and of Lord Kelvin's Royal Commission on the subject. For some six years he was the head of the food inspection subdepartment then set up. During that time a system of control over the wholesomeness of imported foods first came into being, and many contentious questions, such as the definition of whisky and the use of preservatives, were dealt with one by one, on lines accepted by the hygienist and considered reasonable by the trade interests concerned. His war services will be remembered by many, particularly by those on the Eastern fronts, at Gallipoli, Macedonia, and Mesopotamia, who came into contact with the Medical Advisory Committee in which he took part with Dr. William Hunter, the late Sir Andrew Balfour, and others. The post-war generation has chiefly realized his services (or rather, in consequence of departmental practice, has had the benefit of them without personal association) when it has been necessary to look to Ministry of Health reports or publications for judicious summaries of knowledge about infectious or other diseases and their prevention.

Sir George Buchanan's task at the Ministry of Health has been that of an intelligence officer as well as an epidemiologist of exceptional experience and judgement, and his influence in preventive medicine has made itself felt not only in the British Empire but also, and conspicuously, in foreign countries. Buchanan was one of the small body of men of different nationalities which since 1919 has insisted on the opportunities of medicine in the field of international co-operation. It comes often as a surprise to realize the directions in which official work in this country now depends on, or is

at least related to, formal engagements between different nations on health matters. Only last week a list was issued by the Ministry of Health of some 750 ports throughout the world operating the International Agreement of Brussels, 1924, relating to venereal disease, which, initiated by the British delegate at the Office International d'Hygiène Publique in Paris, has made it possible to provide special facilities for the modern and gratuitous treatment of merchant seamen of all nationalities. So, again, when we consult national mortality statistics, we find them dependent on an international official agreement on nomenclature which is negotiated and revised decennially. And, if we have occasion, we realize how regular and rapid is the system of mutual communication about infectious disease incidence between the health departments of the Governments of the world which has grown up in the last ten years, based first on the pioneer work of the Health Section of the League of Nations, and then on the essential International Sanitary Convention of 1926. That Convention has gone far to modernize and rationalize quarantine practice all over the world, and not before it was time; the different departments in the United Kingdom have now consolidated and revised all their port sanitary orders in accordance with it. A striking example of the quiet efficiency of this work was shown last year, when public alarm was aroused at the possibility of yellow fever being carried by the new air routes from parts of Africa, in which it is endemic to the east of that continent and to India. It was only then that many people realized that this and other questions relating to the conveyance of infection by aircraft had been worked out in detail at the international health office in Paris for three years, and that the Hague International Sanitary Convention on Aerial Navigation, 1933, already provided a mechanism by which, so far as willing international co-operation can effect it, this yellow fever danger will be met.

No one is likely to suppose that such business, any more than the British participation in all the useful work which has been done by the Health Organization of the League of Nations since its inception, has been just put through automatically; we have in these days only too much evidence of the prickly character of international discussions and the dangers of international formulae which mean nothing in practice. If Sir George Buchanan has been successful in their negotiation, it has been the result of unsparing labour and an acquired sense of national and international realities, gained by many conferences and missions and travels. For all this a tribute is due to him on his retirement. Last year he was honoured by being elected by the representatives of fifty nations to the office of President of the Permanent Committee of the Office International d'Hygiène Publique in Paris, which carries with it the vice-presidency of the Health Committee of the League of Nations. In leaving the British Government service he will continue to hold these international appointments until the end of next year—a trust with continued satisfaction and success.

THE BLADDER AND ITS SPHINCTERS IN SPINAL CORD LESIONS

The lack of successful attempts to record the function of each of the two vesical sphincters during micturition in man had left a large gap in our understanding of disturbances in the mechanism of micturition. There have been various speculations as to the mechanism of normal micturition, and knowledge concerning functional disturbances of the bladder and its sphincters has had to be built upon this uncertain basis. The pioneer work of Mosso and Pellacani in 1882 on records of intravesical pressure established the presence of waves of vesical contraction during voluntary effort to micturate, and observations on the pressures obtaining in various diseased states have shown the differences between the atonic, relaxed bladder in the state of retention, and the intolerant, powerfully contracting bladder found after some spinal lesions. The relation of vesical pressure to the actual process of micturition has been assumed to lie in the uncertain parallel between the tonic activity of an organ and its phasic function.

Dr. Gordon Holmes has recently published¹ a series of observations on the human bladder during the recovery of vesical function consequent upon complete spinal injuries sustained in warfare. By charting the intravesical pressure during distension of the bladder he traces the emergence of vesical contractility from the state of complete atonicity due to the depression of spinal shock. The tonic resistance of the wall of the bladder to increasing volume of contents becomes gradually more powerful. When fully developed the heightened tone is varied by periodic, powerful, abrupt rises of vesical pressure, which often lead to evacuation of the bladder. He found that such oscillations of pressure arise spontaneously without reference to flexion movements of the limbs, and he doubts the association of vesical contraction and the "mass reflex" of Head and Riddoch. In the same journal² Dr. Denny-Brown and Dr. Graeme Robertson attempt a fuller analysis of micturition in stationary and long-standing complete spinal lesions in man by means of continuous records of vesical pressure. They have succeeded in recording the activity of the internal and external sphincters. Their method, which they have fully described in an earlier communication³ dealing with normal micturition, reveals that the periodic active incontinence eventually established after complete lesions of the cauda equina or spinal cord is an automatic process which depends primarily upon the activity of the local vesical plexus. The detrusor muscle reacts to distension by contraction. The authors believe that this is a local autonomic reflex, for which the adequate stimulus is increasing stretch of the bladder wall. They find that the bladder reacts to a brief stretch by a small, short contraction, which they compare to the tendon jerk in striped muscle. The contraction of the bladder is the more strongly stimulated the more rapid the distension. The

internal sphincter relaxes in a degree proportionate to the amount of contraction of the detrusor, presumably by the same local nervous mechanism. The resulting rhythmical discharge reflects the waves of activity stimulated by distension. Following lesions of the cauda equina such discharge, when fully developed, can secure almost complete micturition by more prolonged contractions and reciprocal-relaxations of the internal sphincter. Patients in this state can usually pass urine by abdominal straining. This faculty makes for progressive recovery from the stage of initial depression with retention, and the authors have demonstrated that it depends on the presence of the above contractile mechanism, which increases the laxity of the internal sphincter.

In the stage of recovery of the spinal reflexes following higher complete lesions of the spinal cord the local mechanism is altered in two ways. The reaction to distension proceeds to much more powerful prolonged waves of vesical contraction; these are interpreted as the effect of a true spinal reflex, which is elicited by a certain degree of development of the local process of reaction to distension. This reflex excites the detrusor to its strongest contraction. The external sphincter is tonically contracted except during reflex micturition, when it is inhibited in the course of contraction of the bladder. Further, it is shown that the external sphincter functions as a rapid and effective means by which micturition is suppressed by other spinal reflexes. The flexion reflex abruptly terminates micturition by concurrently contracting the external sphincter. The clinical facilitation of micturition by perineal stimulation is found to be a reflex effect from the sacral skin segments. This very detailed analysis establishes micturition as a highly co-ordinated nervous process, which primarily depends on distension of the bladder. The hypogastric nerves, which form the sympathetic nervous supply to the bladder, have recently claimed increasing attention in the design of operations to relieve abnormal vesical and pelvic conditions. Denny-Brown and Robertson find that the nerves do not take part in the mechanism of micturition. Their analysis of vesical sensation shows that the hypogastric nerves serve as an inconstant pathway for the pain produced by powerful vesical contraction but that they do not convey the sensation of normal desire for micturition.

The fourth annual report of the National Smoke Abatement Society covers the twelve months ending June 30th, 1933, during which there was a slight increase in financial support and an extension of activities. A larger sale of literature, and better publicity through the general Press, suggest that interest in the subject is growing. The report contains notes of various meetings held in Great Britain. The society republished in the year under review John Evelyn's *Fumifugium*, which first appeared in 1661; more than 2,000 copies have been sold. The proceedings of the conference held in Newcastle in 1932 were subsequently issued in volume form, with papers and discussions in full—a new departure, which has been repeated this year in respect of the annual conference at Sheffield. The offices are at 23, King Street, Manchester.

AN ANTISERUM FOR PFEIFFER'S BACILLUS

There are bacterial infections of such severity as to demand the most energetic possible treatment, for which, nevertheless, no specific remedy is yet available. The reason for this may be the rarity of severe forms of the infection, which precludes adequate therapeutic trial of a serum and lowers the demand for serum to a commercially unattractive level, or it may be some difficulty in producing a consistently effective serum, which often results from the diversity in serological type of the micro-organism concerned. The first of these obstacles distinctly applies to the case of meningitis due to *Haemophilus influenzae* (Pfeiffer's bacillus); the second does not, since it has been shown that almost all strains of this organism recovered from cases of meningitis belong to a single serological type. Pittman,¹ of whose forty meningitis strains thirty-seven belonged to this type, describes the properties of a serum obtained by the prolonged immunization of a horse with these organisms. In mice and rabbits inoculated with living culture the administration of serum reduced or abolished bacteraemia, but an actual curative effect does not appear to have been demonstrated conclusively. The serum also prevented the inflammatory reaction which follows intracutaneous injection of living cultures in rabbits, provided that the dose of culture used was small; this effect is suggested as a means of estimating the activity of a serum. The clinical results obtained closely resemble those of the animal therapeutic tests: of eighteen patients with *H. influenzae* meningitis treated only one recovered, although in six cases the bacilli in the spinal fluid were reduced in numbers or disappeared, and of five cases with bacteraemia the blood became sterile in four. Of all possible manifestations of an infection meningitis is among the most difficult to treat successfully by this or, indeed, by any means; to illustrate this we need only compare the recorded effects of serum treatment in pneumonia with its almost invariable powerlessness to avert a fatal issue in pneumococcal meningitis. To expect a serum, even of the highest attainable efficiency, to exert a curative effect in this disease is therefore optimistic.

RESECTION OF THE STOMACH AND PERNICIOUS ANAEMIA

The hypothesis that pernicious anaemia is associated with, or perhaps even due to, a deficiency in the proper gastric digestion of protein suggests at once that resection of the stomach ought to be followed in greater or less degree by manifestations similar to this disease. No diagnosis of pernicious anaemia can be considered fully established if the stomach secretes free hydrochloric acid, but it is not true to say that all cases of achlorhydria are potentially cases of pernicious anaemia, although microcytic anaemia associated with achylia gastrica is described (Faber). Animal experiments have shown that total gastrectomy leads to anaemia, but not of the macrocytic type. Twenty years ago Moynihan described the onset of anaemia following gastric resection, even when there was no suggestion of malignant disease. From time to time, however, cases are reported in which resection of the

stomach for gastric ulcer appears to be followed by pernicious anaemia, but the general consensus of opinion seems to be that achylia as such does not lead to this type of anaemia. This view is supported by the recent work of Lottrup and Roholm,¹ who made haematological examinations of twenty-three cases in which circular resection of a gastric ulcer had been performed during the period 1909-31, from one to eighteen years having elapsed since the operations. As these authors find the normal average size of red cells to be 8.2μ , they classify cells of 9μ as megalocytes. In no instance was there an unequivocal picture of pernicious anaemia, but 35 per cent. of cases showed a mild anaemia and 20 per cent. a somewhat more severe form (4 to 4.4 million red cells). Some degree of megalocytosis was observed in cases in which free HCl was absent, but it was not associated with colour indices above unity. The authors rightly conclude that resection of the stomach alone does not lead to pernicious anaemia. In the one case in which they considered that some probability of pernicious anaemia existed the blood picture was as follows: haemoglobin 73 per cent., red cells 4.1 millions, colour index 0.88, megalocytes 18 per cent., only slight anisocytosis, and no poikilocytosis. Free HCl was absent. Considerable nervous symptoms were observed, but there were no signs of subacute combined degeneration. In three other cases, in which there was a tendency to megalocytic change, there was no evidence of pernicious anaemia, even many years after the operation.

ALCOHOL AND ACCIDENTS

In a recent article J. Hindmarsh gives an account of investigations conducted by himself and P. Linde in Stockholm.² Every accident case brought to the Maria Hospital between April 1st, 1932, and March 31st, 1933, was investigated for a possible alcoholic factor. The clinical examination was systematized in such a way that the examiner filled in a special form, and in each instance the concentration of alcohol in the blood was estimated according to Widmark's test. The patients were asked to state how much, if any, alcohol they had taken, and when. They were almost invariably willing to comply with this invitation, but, as a rule, the measures they indicated were underestimates. Only those persons aged over 15 who came to hospital within five hours of an accident were thus examined. The average interval between accident and examination was one and a half hours. Among the 283 patients so examined there were 115 (41 per cent.) in whose blood alcohol was demonstrable. Among the 283 were 113 patients suffering from traffic accidents. In fifty of these cases the blood test was positive. All the victims of tramway accidents gave a positive blood reaction, but only half of those who had travelled by motor car or were on foot at the time of the accident. The blood test was positive only in about a third of the patients who had been on a bicycle or motor cycle when injured, and it was invariably positive in persons who had fallen off other vehicles. It is not claimed for this investigation that it gives numerical proof of the degree to which accidents are caused by the misuse of alcohol. A case is, however, made out

¹ *Journ. Exper. Med.*, 1933, lviii, 683.² *Acta Med. Scand.*, 1933, lxxx, 243.³ *Svenska Läkarsällskapets Föreläsningar*, November 30th, 1933, p. 515.

for assuming that there must be some causal relation between alcohol and accidents, judging by the frequency with which consumption of the former, often in large quantities, precedes the latter.

MAGIC, MEDICINE, AND QUACKERY

Many hard things have been said about unqualified practitioners, but their motives have seldom been subjected to detached scrutiny. Dr. John Rickman, in his address from the chair to the medical section of the British Psychological Society on January 24th, made an interesting contribution to the study of quacks and quackery from the standpoint of psycho-analysis. The search of medical men for truth has, he explained, led towards progressively greater objectivity, the highest goal being the purely objective attitude. The mind, in its struggle to master the excitement generated by the instincts, appropriates external objects to represent its own spiritual potentialities and attaches them to the ego, so as to spread the excitement over a wider field and bear it more easily. In primitive magic the medicine man treats a case by taking the evil demon out of the patient into himself and there attacking it by the aid of his own ancestral spirits. The priest, representing a notable advance in this evolution, never identifies himself with the spirits, but stands, as it were, between the patient and the powers above and below, acting as an interpreter. In magic the spiritual elements of the mind, like the forces of Nature, are related to one another by violence; in religion their relations are more developed—they behave more like real people, organized and well-disposed human beings, and their nature carries more possibility for progressive sublimation. The Greek physicians, as early representatives of scientific medicine, came much nearer towards objectivity through the passionate love for the human body which characterized the Greeks and which was perhaps the most important factor in the early development of the healing art. Among the Greeks injury and disorder of function induced pity instead of stirring up belief in demons. They had learned to guide their own energies on to the outer world in a constructive way. The modern scientific medical man achieves the same or a greater objectivity. He has learnt to train and use his primitive instincts; he therefore no longer feels the inner anxiety that comes from failure to harness instinctive functions, and so he has arrived at a sense of the unity of the personality, and, as a corollary, a sense of the unity of the outer world. His work is as little as possible subjective and exciting to his emotions; he patiently matches one set of symptoms with another until he can see a clear picture, with points of resemblance and difference, of two sets of objective facts. The wish to heal others is the product of a complicated series of early fantasies, including the wish to cut up and explore the insides of other people, to stop them from having children, to make children oneself, to regulate the breathing, eating, and sleeping of oneself and others in magical ways. Between the quack and the doctor lies not so much difference in learning as difference in the way in which each controls these wayward fantasies. Crude impulses are controlled by the building up of a super-ego or ideal by an internal discipline of the emotional life. The model for the process may be an admired person

or an abstraction such as "the profession." Quacks, as defined by Dr. Rickman, are persons who refuse to submit to the discipline of a profession while claiming the privileges of a professional man. The discipline of the medical curriculum is not a guarantee that the qualified man will not revert to magic, but it trains him to control his crude fantasies. Patients generally go to quacks because the neurotic factor in their troubles has not been recognized and their treatment has been incomplete. In this department of its work the medical profession and its curriculum as a whole have fallen short of objectivity, and the remedy is to include in the curriculum a study of neurotic factors.

THE LEAGUE AND NARCOTIC DRUGS

Whatever may be the future of the League of Nations, and even if it were to disintegrate, some provision will have to be made for carrying on such work as that which the League has organized and supervised for the limitation of the traffic in dangerous narcotic drugs to medical and legitimate purposes. The successive Conventions on that subject have transferred the question from the national to the international field, and the machinery thereby established, through more than fifty ratifications of, or accessions to, these conventions, has created a record among the League's activities. The Assembly of the League has noted with satisfaction these measurable achievements, and is satisfied that the quantities of the scheduled narcotics manufactured by the licensed firms during recent years approximate to the quantities required for legitimate consumption. On the other hand, the Assembly was greatly concerned with the danger arising from the development by international traffickers of clandestine manufactories at the very time when the control of legitimate commerce was showing such marked improvement. The Permanent Central Opium Board, at its recent eighteenth session, was impressed by the large stocks of opium held by the Government of India, and instructed its president to ask for information on the subject from the Indian representative on the Opium Advisory Committee. The accumulation of considerable stocks of narcotic drugs in Hungary also demanded investigation, while the increasing number of seizures of contraband drugs in France was held to be due to the greater strictness exercised by the newly established "French Narcotics Bureau." A proposal has been considered by the Assembly to define by Convention a new international crime, on the lines of the Counterfeit Currency Convention, whereby punishment for acts not all committed in the same territory could be inflicted, and extradition facilitated. Slow progress was reported in preparation for the proposed conference for limitation of production of the opium poppy and the coca shrub, a problem which is clearly essential to any radical restriction of the raw materials of narcotics to strictly legitimate usage. It will be remembered that the League, on the advice of its Health and Opium Committees, came to the conclusion that the world requirements for medical and scientific purposes were: of morphine 9½ tons, of heroin 2 tons, and of cocaine 5½ tons. The newly constituted Supervisory Body, set up under the Limitation Convention of 1931, has recently reported on the estimates which have been submitted by forty-five countries of their requirements

of these drugs during the current year. In the case of twenty-three countries which failed to furnish estimates the Supervisory Body has itself framed the estimates. The figures of world requirement for the five principal drugs, based on these estimates, are: morphine 40 tons, heroin $1\frac{1}{2}$ tons, codeine 26 tons, dionine $2\frac{1}{2}$ tons, cocaine $5\frac{1}{2}$ tons. It must, however, be remembered that heroin, codeine, and dionine are derivatives of morphine, and although the two latter have not hitherto been brought into the same conventional control as the others, the morphine required for their manufacture is included in the total estimate of 40 tons of that alkaloid. The amount required for conversion into heroin, codeine, and dionine is stated to be $29\frac{1}{2}$ tons, of which about 28 tons are for the production of codeine and dionine alone. These two alkaloids have been claimed to be "not habit-forming drugs," although they are convertible into such. Codeine was indeed included in the original draft of the Hague Convention of 1912, but was struck out at the instance of the German delegation. If the amounts for "conversion" are subtracted from the 40 tons of morphine—the total estimates thereof for 1934—it will be seen that the world requirements for this year do not differ widely from the standards laid down by the League of Nations. The statement now issued by the Supervisory Body represents an organization, on a world-wide scale, of the narcotic drug industry and the trade in and consumption of such drugs. In the case of the manufacturing countries the estimates furnished determine the maximum limits within which manufacture may take place under the conditions laid down in the Convention, and the extent to which the parties to the Convention may export narcotic drugs, not only to each other, but also to States not parties to the Convention.

THERAPEUTIC PROPERTIES OF SNAKE VENOM

In a recent survey of the present position of snake venom as a therapeutic agent Dr. A. Ravina¹ points out that the analgesic properties of this substance were recognized by the homoeopaths long ago. Two lines of research, one experimental, the other clinical, are now being pursued in Paris with some curious results. The late Professor Calmette and his assistants have worked with a dried preparation obtained from the Pasteur Institute at Saigon. Their experimental animals were mice inoculated with a particularly virulent adenocarcinoma. Whether this new growth was spontaneous or grafted the injection of the snake venom directly into it was sometimes followed by its breaking down and a discharge, after which recovery took place in certain cases. The early death from septicaemia of some of the mice reacting most favourably to this treatment obscured the issue; and, while some of the results appear promising, these experiments can certainly not be described as convincing. As regards the investigations conducted at the Salpêtrière in Professor Gosset's service, the 115 cases about which reports have been issued form a very mixed collection, including many patients with advanced malignant disease. Some were inoperable, and in others various therapeutic agencies had already proved futile. But though in most of them there was little or no sign of

cure, it was often noted that considerable relief from pain followed the injections, which were given every third to every fifth day. As the cobra venom is administered in Paris in doses provoking neither suppuration, nor a general reaction, there is the more reason to pay attention to the isolated cases in which this treatment is followed not only by relief of pain, but also by cicatrization and other signs of healing. There is, for example, the case just published by A. Orticoni,² whose patient, between 70 and 80, was suffering from an epithelioma of the rectum. A few hypodermic injections of cobra venom changed the general and local conditions for the better. Peck and Goldberger³ have found that snake venom has a beneficial effect in cases of uterine haemorrhage which had proved refractory to other methods of treatment.

SALESMANSHIP

"Salesmanship" is defined in the *Oxford Dictionary* as "the condition or character of being a (good) salesman," and two quotations are given from novels of the 'eighties. Perhaps a closer definition of the word to-day would be "the faculty whereby one person induces another to buy something he does not want." Tradition abounds with examples of this particular branch of the commercial art, for is it not safe to assume that the answer to the question "D'you want to buy a watch?" is seldom "Yes"? Again, a contemporary humorist tells us of a customer who, visiting an old clothes shop in a certain London district in quest of a pair of golf trousers, found himself compelled to buy also a patent putter, a fireman's helmet, and a bowl of goldfish. An example of salesmanship on a larger scale is afforded by the recent practice of persuading simple-minded doctors to put their names down for an encyclopaedic work of reference. In this way several of our readers have found themselves committed to paying some £20 for a set of volumes which, on mature reflection, they find they do not want. Likely customers are approached in person or by letter, or by both methods, busy surgery hours being generally chosen for the personal interview. Too often the preoccupied doctor puts 30s. down and signs a printed form "not subject to cancellation" which contains a promise to pay the balance in monthly instalments. A circular letter emphasizing the value of the offer, and the singular good fortune of the prospective buyer in being chosen to receive it, includes the phrase "this is not philanthropy, but approved modern business procedure." To those wholly unfamiliar with American business methods such candour may be disarming, but we like to think that the majority of British practitioners, even under the spell of salesmanship, will refrain from purchasing goods, however excellent, for which they have no real use.

The Prince of Wales has consented to become Patron of the London School of Hygiene and Tropical Medicine, with which is incorporated the Ross Institute. This announcement was made at the staff and students' dinner by Sir Austen Chamberlain, chairman of the Court of Governors.

DIET IN RELATION TO DENTAL STRUCTURE AND DISEASE

The Medical Research Council issued last week a report¹ that completes Mrs. May Mellanby's account of her important researches into the influence of diet on the teeth. The scope of this survey is indicated by its title: *Diet and the Teeth: an Experimental Study. Part III. "The Effect of Diet on Dental Structure and Disease in Man."* Its appearance is a noteworthy event, and it has already received much attention in the public press. The significance of the main conclusions arrived at by Mrs. Mellanby is discussed in a leading article at page 246.

The report consists of 180 pages of letterpress, with 46 plates and 56 tables. The first half is devoted to an account of the structure and development of human teeth. The author shows that the tooth structure which has generally been accepted as normal, and which is indeed the structure usually seen, is markedly defective when compared with the teeth of healthy animals or with the best human teeth. The following subjects are dealt with in turn: normal development and structure; abnormal development and structure; dental caries; the relation between structure and dental caries; and the defensive reactions of teeth.

Mrs. Mellanby next gives an account of the influence of diet on the incidence of caries in children, and in this chapter are summarized the results of a series of large-scale dietary experiments which she conducted in Sheffield and in Birmingham. The report concludes with an account of the racial distribution of caries, which shows that dental caries is very widespread and has been prevalent in many communities since the dawn of history, but that, on the other hand, there are a number of populations living under primitive conditions which are almost free from caries. Incidentally it is clear that this immunity to caries is not a racial characteristic, because primitive races develop caries when they adopt the diet of civilization, while certain white communities living under primitive conditions are free from caries.

PRINCIPLES OF NUTRITION

Her advice to civilized people if they want to have good teeth may be summarized in four sentences: Breast-feeding up to a year or more, so long as a supplementary diet, including some iron and vitamin C, is given after about the sixth month. More milk, eggs, cheese, animal and fish fats, and vegetables, and less cereals. No cereals at all for the very young. Cod-liver oil, or some other source of the fat-soluble vitamins A and D, to be given to all infants and children.

"It has been shown that perfectly calcified and regularly arranged teeth can be produced by including in the maternal diet during pregnancy and lactation, and in the diet of the offspring at the time of dental development, substances containing much fat-soluble vitamin, calcium, and phosphorus such as milk, egg-yolk, fish, and animal fats; the vitamin D can also be obtained by exposure of the skin to sunlight or other sources of ultra-violet radiation; that cereals, especially those rich in embryo such as oatmeal, tend to produce badly developed (hypoplastic) teeth and call for a correspondingly larger supply of calcifying foods for good development. It has been further established that the teeth of the majority of children in the British Isles are imperfect in structure and have a roughish surface; that dental caries is more likely to attack such teeth than perfect teeth with normal enamel and dentine and a comparatively smooth surface; that the resistance of teeth to caries can be increased independently of their original structure by giving a diet of high calcifying activity; and, on the other hand, that the resistance can be decreased by a diet rich in cereals and of low calcifying properties.

"Another outstanding feature of the experimental work was the demonstration that a deficiency of vitamin A or carotene played an important part in the development of the periodontal tissues and in the control of the onset of periodontal disease, including pyorrhoea. Up to the present time these observations have not been extended to man, but that they can be so extended is strongly supported by the distribution of this disease in different races."

NORMAL DENTITION IN CIVILIZED PEOPLE

There is one consideration arising from the statistical results that may appropriately be mentioned here. Table IV shows the state of deciduous teeth from varying sources. The most satisfactory teeth were a group obtained from private sources, and in these the incisors were satisfactory, since 72 per cent. were classed as normal; on the other hand, only 23 per cent. of the canines and 10 per cent. of the molars in this same group were found to be normal in structure, while 50 per cent. of the second molars were classed as very hypoplastic. It appears very doubtful whether this group could be looked upon as representing a true average of middle-class children, for the teeth are most likely to have been obtained from families possessing more than the ordinary knowledge of diet and taking a particular interest in dietetic problems. On this assumption the results would suggest that the deciduous molar teeth are structures which are showing definite signs of degeneration in white races. Such an idea gains support from the well-known fact that no small proportion of third permanent molars show gross signs of maldevelopment. Considerations of this kind raise a certain doubt as to whether a dentition that is normal according to Mrs. Mellanby's standard is a possible average attainment under any conditions of to-day, or whether we now have to deal with degenerating structures that can only be kept in a moderately satisfactory state by means of special dietary precautions.

DENTAL CARIES A PROBLEM OF NUTRITION

The first of Mrs. Mellanby's larger reports on diet in relation to dental structure and disease, dealing with the jaws and teeth of puppies, was reviewed in the *British Medical Journal* of February 15th, 1930 (p. 292), the second, on the teeth of other mammals, was reviewed on March 21st, 1931 (p. 502), and a short interim statement, on diet and caries in children, on October 3rd, 1931 (p. 615). These documents, together with the survey now published, constitute a most remarkable monograph on the physiology and pathology of the teeth of animals and man.

In the work described in this concluding volume of the series the experimental results set out in the first two reports were extended to children, with a view to determining whether dental disease, and especially dental caries, was also in the main a problem of nutrition, and, if so, whether this scourge of civilization could be prevented by eating and absorbing the right kinds of food.

Her earlier work went to show that susceptibility to dental caries depends in the main upon dietary factors operating at the time the tooth is first formed; that ill-formed teeth are those most vulnerable to bacterial attacks; and that throughout life, but particularly during the first months and years, certain articles of food favour resistance to decay while others act in the opposite direction. By the light of these and later investigations she has been able to lay down general principles of human nutrition whose aim is "the formation of more perfect teeth and surrounding tissues, more regularly arranged in well-grown jaws. With better structure of dental tissues and increased resistance to bacterial invasion there is every reason to believe that both dental caries and pyorrhoea will cease to be the scourge they are at the present time."

THE HEALTH OF THE ARMY

REPORT FOR 1932

The report on the health of the Army for 1932¹ reveals a highly satisfactory position. Not only was the admission to hospital rate (412.5 per 1,000 of the strength) the lowest on record, but the invaliding and constantly sick rates (7.92 and 21.56 per 1,000 respectively) and the average individual period of sickness (7.89 days) were the lowest recorded since the war. All the more important diseases, including malaria, influenza, dysentery, tonsillitis, sand-fly fever, dengue, and venereal diseases, participated in this decline. Definite factors in this improvement were undoubtedly the increasing attention paid to preventive measures, and the interest taken by officers of the Army Medical Services in the scientific side of medicine.

ANTIMALARIA MEASURES

The malaria incidence has fallen from 99.8 per 1,000 in 1921 to 28.4 in 1932; but in India, it has to be admitted, this infection still continues to merit its designation as the scourge of the Army. In 1932 the admissions to hospital of malarial patients formed 14.5 per cent. of the total admissions, and this represents hospitalization only; it does not include out-patient attendance, nor indicate the degree to which the disease adversely affects the general physical efficiency. While the fact that there are between four and five thousand annual admissions for malaria out of a strength of 55,000 is disturbing, it is reassuring to note that the steady, if slow, improvement of recent years is being maintained. This was especially evident in 1932 in the case of the Northern Command in India, where malaria plays more havoc among the troops than in any other area in that country. Here the admission rates fell from 138.4 in 1931 to 91.5 in 1932, a noteworthy contrast with such years as 1925-7, when the figure was always over 200. The lowest record as regards malaria before 1932 was reached in 1928, and for various reasons it had been expected that the year under review would prove to be definitely worse. Climatic conditions had militated against the disease in 1928, but had favoured its spread in 1932. Financial restrictions in the latter year had brought new antimalaria engineering work to a standstill, and civil disturbances in various places had subjected the troops to very hard work under adverse weather conditions and in circumstances which greatly hindered antimalaria measures. The factors which outweighed these hostile agencies are recorded as follows. Steadily increasing interest in malaria field work has resulted in officers performing their duties in this respect with enthusiasm and hopefulness, even though hampered by lack of funds and the pressure of other duties. In this connexion a warm tribute is paid to the value of the instruction courses held annually at the Ross Field Experimental Station at Karnal.

The more extensive and skilful employment of plasmoquine in 1932, as compared with that in 1928, is believed to have played a very considerable part in reducing the incidence and morbidity due to malaria. Accumulating clinical and statistical evidence supports this view, but only a tentative opinion to this effect is advanced in the present report because the full results of the first year's systematized administration of this drug are not yet to hand. The whole question of the prevention and treatment of malaria is discussed in detail. With a view to greater accuracy in the differential diagnosis of "fresh" and "relapse" malaria, a circular on diagnosis was issued from Army headquarters to all medical officers. The prophylactic value of quinine is rather doubted on the whole by Army experts; evidence in favour of plasmoquine was obtained, but the lower doses were ineffective, and the toxicity of higher doses led to doubts about the value of employing this drug on a large scale. As a therapeutic agent, however, plasmoquine established its position during the course of 1932. The average relapse rate for India during the quinquennium 1927-31 was 277 per

1,000. Figures for 1932 in the case of plasmoquine-treated patients ranged from 20 to 47 per 1,000, and it is hoped confidently that the admissions for relapses during 1933 will show a very pronounced reduction, with a correspondingly far-reaching effect on the health of the Army. This drug was usually administered with quinine, and sometimes with atabrin, the new therapeutic agent which is winning favour. Atabrin is generally held to be as powerful in action as quinine, but slower in getting to work. No toxic sequelae of any importance have yet been reported, even when it was employed in combination with plasmoquine. The Army practice is to administer the drugs consecutively, not simultaneously. Tribute is paid to the clinicians and epidemiologists who have given particularly valuable help during the year. An adaptation of the peace mosquito net for use in the field has been approved, and the provision of mosquito-proof tents is now possible. Experimental trials of an outfit designed for the field diagnosis of malaria and dysentery are now nearing a successful conclusion.

HYGIENE AND NUTRITION

The Army's need for a higher, and therefore more expensive, standard of sanitation than is thought necessary in civil life is particularly apparent in connexion with the prevention of respiratory infectious diseases, which constitute one of the chief causes of sickness and inefficiency. Their predisposing causes are accentuated in communal military life in a way which is rather exceptional in a civil community. The barrack rooms are alternately scrubbed and swept, giving at one time a humid hot or cold atmosphere and at another time a dust-laden atmosphere, the dust eventually settling on the pillows and sheets and eating utensils, to be later inhaled or swallowed by the occupants of the rooms. The heating of the barrack rooms is differently effected by open fireplaces round which the men congregate, and spray each other with whatever organisms they may be carrying in their respiratory tracts. The prevention of these conditions, it is remarked, would check the spread of infectious respiratory diseases. It comprises the provision and adoption of modern cleaning methods by the use of vacuum apparatus, and the adequate warming of barrack rooms by central heating. Both these procedures are recurring sources of expense, unfortunately, but it is believed that they would not be more expensive than the loss of man power and the deterioration in health which at present occur as the result of their not being employed. The Army food ration, judged from the civilian standpoint, is considered to be adequate as regards its constituents; the problem of utilizing it to its full value is almost entirely one of good housekeeping by the unit. The number of courses of instruction at the Army School of Cookery is insufficient to maintain an adequate flow of regimental cooks, and an increase in the establishment of the school is under consideration. The decline in the purchasing power of the troops has been countered by the introduction of a measure whereby the messing cash allowance now moves on a sliding scale which is regulated by the official index figure governing the cost of living (food). A mild-cured bacon has replaced the previous hard-cured salt variety, a change which has proved most popular, even in semi-tropical countries, but issues of dried milk were unfavourably received by the troops.

Special attention was directed to the high incidence of tonsillitis, the second greatest cause of admissions to hospital among officers, and the third greatest cause among other ranks, the average figures being 14.6 and 31.5 per 1,000 respectively. The Joint Medical Services Committee appointed a subcommittee of the three services to study the situation from statistical, environmental, and aetiological standpoints. A detailed report eventuated which is now under consideration. The desirability is suggested of attempting to obtain evidence by mass investigation as to the relative importance of dormitory infection, methods of washing messing utensils (the saliva theory), and nutrition. A comparative study was made of such service schools as those at Shotley and St. Vincent (Royal Navy), Chepstow (Army), and Halton (R.A.F.), and some light

¹ H.M. Stationery Office. 1934. (2s. 6d. net.)

was thrown upon the problem of infection. While evidence was obtained that tonsillectomy diminished greatly the incidence of local throat diseases, it appeared also that it increases the susceptibility of the patient to some other diseases. Further investigation is recommended in respect of the possible association of dental and oral sepsis with respiratory infections, and of the relation of disease to growth rates and nutrition. There was a suspicion of vitamin deficiency in all the dietaries.

HEALTH OF COMMANDS AT HOME AND ABROAD

The present report contains the usual statistical information about the health of the various commands at home and abroad. Judged by the average sick time to each soldier, the commands with the highest ratio of inefficiency were Aden (14.51 days), China (12.15 days), Jamaica (11.69 days), and Ceylon (11.47 days). Those with the lowest ratios were Malta (7.6 days), Mauritius (6.46 days), and Bermuda (5.62 days). The number of invalids discharged from the Army in 1932 was 1,439. The amount of venereal disease again fell most satisfactorily, including this time the incidence in China, where there are special difficulties in the way of its prevention. The steady annual growth in the number of admissions for scabies, as compared with an almost equally steady decrease of venereal disease, led to an inquiry in commands as to possible reasons for this change. It was found that most of the infestations occurred in men returning from leave; that the condition was more prevalent in the civil population heretofore; and that, whereas the decrease in venereal disease was due to the education of the soldier and the public in methods of prevention, these methods did not apply to scabies. Although there was an increase in the admissions for nervous diseases (1,283, a ratio of 7.1 as compared with 6.6 last year), the numbers of invalids sent home and of invalids finally discharged were substantially reduced. An investigation of cases of mental disease at Netley confirmed the view that the causes of insanity in the Army are the same as those in civil life, and that military service in itself has no direct bearing on the causation of mental disorder.

THE CAUSE OF SILICOSIS

A debate on silicosis in the mining industry took place at a meeting of the Institution of Mining and Metallurgy on January 25th. It was opened by Mr. W. R. JONES, D.Sc., of the geological department of the Royal School of Mines.

Dr. Jones described his investigations of the mineral residues obtained from twenty-nine lungs, each lung being from a person whose death had been certified as due to silicosis; five of these were from workmen in the pottery industry and twenty-one from underground workers in British collieries. The dust obtained from every one of these lungs consisted of minute acicular fibres of sericite—a hydrated silicate of aluminium and potassium, sometimes called secondary white mica. The mineral was abundantly present in all the rocks and materials which gave rise to the inhaled dust causing silicosis in these cases. Silica in the uncombined state, as quartz, was also present in these residues, but numerically the fibres of sericite predominated very greatly over the quartz particles. He submitted that silica in the uncombined state was not the chief cause of silicosis in the cases described, but that the presence of fibrous minerals, chiefly sericite, in aggregates which during the impact of drilling, blasting, or crushing became freed into the atmosphere as individual fibres, enabled sufficient material in course of time to enter the lungs to cause the disease. Whether the minerals acted as mechanical irritants causing the growth of fibrous tissue or induced chemical changes, as maintained by certain pathologists, was beyond his province.

Professor J. S. HALDANE dissented most emphatically from some of Dr. Jones's conclusions. To his mind the perfectly clear evidence which incriminated uncombined silica had never depended on the nature of the dust found

in the lungs at death, but on the history of prolonged exposure to dust containing a high proportion of silica in the uncombined or free state. Dr. Jones had given instances of cases in which he believed that undiluted dust of highly siliceous rock or even perfectly pure free silica was breathed without harm resulting, provided that no sericite was present. Professor Haldane thought that in every one of these cases he was entirely mistaken. The dangers of crushing pure quartz without scrupulous precautions against inhaling the dust had long been known, and it was the success of the precautions enforced by law, and most certainly not the harmlessness of the dust, that was shown by the safety with which quartz was now crushed. He also protested emphatically as a physiologist against the idea that the lungs might be regarded as a sort of geological dust trap which simply accumulated dust. Through the activity of living phagocytic cells and ciliary action dust was continuously removed from every part of the lungs, but when dust mainly of pure silica was breathed there was a breakdown of the normal cleaning process, and at the same time the lungs became very susceptible to tuberculous infection.

Dr. HERBERT H. THOMAS, petrological expert to the Home Office, confirmed Dr. Jones's opinion of the mineral he had found in the silicotic lungs. The residues were definite foreign mineral particles of mica-like material, having a refractive index, by-refrindex, and all the other physical properties consistent with the mineral sericite. Sericite was possibly the primary or even the sole cause of the silicotic condition.

Professor E. H. KITTLE of St. Bartholomew's Hospital said that he was not very much impressed with Dr. Jones's negative evidence—the fact that silicosis did not occur in situations in which sericite was not present. One reason for his scepticism was that he knew too much about death certificates to place very great reliance on the Registrar-General's returns. As an experimental physiologist he thought he had ample proof that crystalline silica, flint, pure quartz, and substances other than sericite were capable of producing lesions in the body which he recognized as characteristic of the silica reaction. On the other hand, he had had far greater success in producing experimental lesions with kaolin than he had had with pure quartz or other forms of pure silica. In his own experience in this country pure silicosis was a rare disease. He was more and more impressed with the infective factor in the production of this condition. The specimens sent to him were nearly always those of infective silicosis, and the infecting organism most commonly the tubercle bacillus.

Dr. E. L. MIDDLETON, medical inspector of the Home Office, said that he would not place any reliance on a hypothesis based on the assumption that dust particles must be of a certain shape in order to reach the alveoli. He had collected many samples of atmospheric dust in manufacturing processes, and it appeared quite possible to have high concentrations of dust of quartz with particles under two microns in size, any or all of which could reach the ultimate recesses of the lungs. It was important to realize that quartz dust was capable of reaching the pulmonary alveoli as well as sericite, and even along with it. There was need, he added, for a comprehensive investigation into the mineral composition of the materials which gave rise to dust wherever cases of silicosis were known to occur.

Sir JOHN FLETT, director of the Geological Survey, a medical man, declared that finely divided silica was a very dangerous substance. It was not, in his belief, the nature of the mineral that determined its dangerous character, but the shape of the particles. These fine, metal-like acicular particles were especially dangerous, because, with the movement of the bronchi and alveoli of the lungs, it was very difficult for them to come to rest. He had examined a large number of coal miners' lungs, but the coal particles tended to be cubical or rounded in shape, and therefore were less dangerous than the pointed particles of sericite and asbestos. Flints, especially when heated, also tended to break up with very fine needle-like points.

Many more experts were eager to continue the discussion, which was adjourned until February 15th.

Scotland

Incapacitating Sickness in Scotland

A report¹ dealing with incapacitating sickness among the insured population of Scotland during the year July 1st, 1931, to June 30th, 1932, has been issued by the Department of Health for Scotland. The data from which this is prepared are derived from the records of approved societies periodically furnished to the Department, and include tables of the incidence and duration of various disorders, as well as conclusions drawn from these. The statistics do not show any very marked divergence from those for the previous year. There was a slight fall of 2.1 per cent. in the total duration of incapacitating sickness in the insured population as a whole, but while there was a decrease for men amounting to 6.1 per cent., there was an increase of 4.6 per cent. for women—that among single women being 5.1 per cent. and among married women 3.2 per cent. There was also a slight drop in the incidence of sickness represented by the number of completed cases of incapacity. For the whole insured population the decline amounted to 5 per cent., caused chiefly by a diminished incidence among men amounting to 8 per cent., although for women there was a rise of 1 per cent. With regard to the average duration of incapacity, there was an increase of 3.1 per cent. for the total insured population. The decline in sickness was chiefly due to a diminution of respiratory diseases, accidents, skin conditions, gastritis, and anaemia; on the other hand, an increased amount of incapacity had been ascribed to tuberculosis, malignant tumours, heart disease, gastric ulcer, appendicitis, hernia, and kidney disease. During the year the number of completed cases of incapacity was 359,511, including 228,030 men and 131,781 women. The total duration of incapacity for these cases amounted to 16,705,885 days, including 10,024,155 days for men and 6,681,730 days for women. The incapacities during the year were equivalent to 20 per cent. of the total insured population, that of men (189 per 1,000) being lower than that of women (234 per 1,000). The average duration per completed case of certified incapacity was 46.43 days, the female average being higher than the male. For the year 1930-1 the number of completed cases of incapacity was 378,742, so that the diminution as represented by the figure for 1931-2 was equivalent to 5 per cent. This diminution was due to a decline of incapacity among men represented by 19,883 cases, or 8 per cent., as against an increase of 1,195 cases, or 0.9 per cent., among women. The increased incidence among women occurred in the unmarried group. The total period of time lost (16,705,885 days) was 357,838 days less than in 1930-1, or a decrease of 2.1 per cent. There was a greater relative decline in the number of cases than in the total days of sickness, so that the average duration per completed case was greater in the year 1931-2 than it was in 1930-1, the average duration having increased from 45.05 to 46.43 days. A table of the certified causes of sickness shows that the chief incapacitating factor was diseases of the respiratory system, accounting for 39.1 per cent. of all the cases. This was followed by diseases of the locomotory organs, accounting for 11.34 per cent., and diseases of the digestive system, 10.66 per cent. Violence accounted for 9.3 per cent., and skin conditions (chiefly suppurative and inflammatory diseases) for 8.84 per cent. With regard to incidence rates in the two sexes, the greatest relative divergencies were found in anaemia,

debility, nervous disorders, infectious diseases, and appendicitis, the incidence rates being much higher in females than in males. On the other hand, hernia, gastric ulcer, accidents, malignant tumours, cerebral haemorrhage, and septic skin conditions were appreciably more numerous in men than in women. In single women as compared with men higher incidence rates with lower average durations were found for anaemia, debility, and neurasthenia, and a higher incidence with also a higher duration in infectious diseases, diseases of the respiratory tract, and appendicitis. In married women as compared with men a higher incidence and higher average duration were found for tuberculosis, pernicious anaemia, goitre, and heart disease. The relation subsisting between average duration of incapacity and age was well defined in the male sex, for at ages under 20 the average duration of incapacity was twenty-three days, and in each succeeding age group the duration increased in amount, reaching 136 days in the last age period of 60 to 64. The same relation with minor variations was observed among the female insured. Some interesting facts are given regarding the geographical variations of sickness. The incidence of incapacity in the burghs was found to be 201 cases per 1,000, while in the counties it was 203. On the other hand, the average duration was substantially higher in the burghs than in the counties. The highest rates for incidence of incapacity were found in Airdrie, Hamilton, Kilmarnock, Perth, and Falkirk, where the numbers were equivalent to at least one out of every four insured persons; the lowest were found in Greenock, Inverness, and Clydebank, with rates respectively of 142, 161, and 162 per 1,000 insured. The duration of sickness per person was lowest in Greenock, Ayr, and Edinburgh, and greatest in Airdrie, Arbroath, and Perth. Neither the incidence of incapacity nor its duration appears, therefore, to have any relation to the industrial character of a district. By dividing the country into three belts of north, central, and south, it was found that incapacity was most frequent in the central industrial belt, lowest in the north, with the southern border district intermediate, but the average duration of incapacity was in the reverse order, that for the central region being lowest.

Education Health Service in Glasgow

The annual report, by Dr. G. Arbuckle Brown, on the medical inspection and treatment of school children for the year ended July 31st, 1933, has now been issued by the public health department of Glasgow. Details are given of the routine medical inspection of 46,683 children, mainly at the age groups of 5, 9, and 13. In addition 1,485 children in special schools for physical and mental defectives were examined. The balance of 122,226 medical inspections during the year was made up of 14,840 examinations of children specially presented by the teachers on account of suspected defect, the re-examination of 23,275 children found to be "abnormal" on a previous occasion, and 35,943 special inspections for various purposes. The heights and weights of the children compared favourably with previous records; the averages for the last quinquennium of children of various ages were in nearly every case higher than the corresponding figures for the three other five-year periods, omitting the war years, since 1910. The following conditions were in 1933 as good as, or better than, any records since 1919: clothing—in need of repair 0.3 per cent.; dirty 0.2 per cent.; verminous head, 0.2 per cent.; dirty body, 0.4 per cent.; verminous body, 0.3 per cent.; nutrition—bad 3.6 per cent., very bad 0.1 per cent.; good visual acuity, 77.4 per cent.; rickets, 2.5 per cent.; Such percentages tend to vary slightly from year to year, but, the report states, only occasionally have the figures for 1933 been improved upon. An analysis of the physical condition of the children based on the records of the

¹ Report on Incapacitating Sickness in the Insured Population of Scotland during the year 1st July, 1931, to 30th June, 1932. H.M. Stationery Office, 120, George Street, Edinburgh. (9d. net.)

routine medical inspection of 32,495 children shows that 94.4 per cent. were free from any irremediable defects, 4.5 per cent. suffered from acquired irremediable defects, 1 per cent. had congenital irremediable defects, and 0.1 per cent. had other irremediable defects, or combinations thereof. The number of children receiving medical treatment at the school clinics has increased since 1932; the total seen, and, for the most part treated, included the following: diseases of the ear, 4,689; diseases of the eye, 5,152; skin, 18,856; other minor diseases, 14,335; artificial light treatment, 478; defective vision, 9,230; defective teeth, 20,797; tonsil and adenoid operations, 1,374; deformities (exercises, massage, appliances, etc.), 955. This work involved 472,211 attendances of children at school clinics. Although these figures indicate an increase of between 3 and 4 per cent. over the figures for the previous year, there was no evidence of any real increase of disease or defect among the children. Throughout this section of the report there is evidence that the more serious conditions from which children attending ordinary or special schools suffer are diminishing, and that the increase in the treatment figures is due to minor conditions now receiving attention in the school clinics because of the adverse economic circumstances of the parents.

Edinburgh Medical Missionary Society

At the annual meeting of the Edinburgh Medical Missionary Society Dr. R. A. Fleming said that the society now had a greater number of students in training than ever before. There was a deficit on the past two years' working amounting to over £1,700, but owing chiefly to a legacy this had been reduced to about £800. The society, however, required increased financial support. Referring to the training of medical students for mission work, Dr. Lasbrey said that the supply was by no means equal to the demand, and many societies were urgently in need of men and women doctors at the present time. Dr. Taylor emphasized the need for better equipment of hospitals in the mission field, and gave as an example of the difficulty of medical work in India the fact that in the district where he worked there were less than ten doctors, with some thirty or forty other persons partly trained in medical work, for a population of about one million.

Ireland

Welfare Work for the Blind

Professor T. G. Moorhead, in the course of a long and interesting lecture outlining the work that is being done for the welfare of the blind in Great Britain and Ireland, stated that there were about six million blind people in the world, including about 63,000 in Great Britain, and in the Irish Free State certainly not less than 4,000, or one in every 800 of the population. It had been calculated that at least one blind person in every three was capable of working and earning a livelihood, so that, if blind people were given the opportunity, about 20,000 in England would cease to be a drag on the community, while over 1,200 in the Free State would be able to contribute to their own maintenance. To Dr. Armitage belonged the great credit of realizing the capabilities of many blind people, and their power not merely to interest themselves, but to support themselves in many professions and occupations. He was born in 1824, and, as a medical student, suffered from some trouble with his eyes. At the age of 36 he was compelled to abandon the practice of a London consultant owing to increasing dimness of his vision. As far as Ireland was concerned little welfare work on behalf of the blind was done until 1911. In that year an Irish solicitor, Mr. Rochford

Wade, became blind, and at once started to work on behalf of his fellow-sufferers, using his office in Lower Gardiner Street, Dublin, as a centre. He founded the Hibernian Blind Association, and in 1913 a branch of the National Institute for the Blind was established in Dublin, with Mr. Wade as secretary. The Hibernian Blind Association ceased to exist in 1925, and there was a gap in welfare work until 1931, when the National Council for the Welfare of the Blind of Ireland was established through the energy and initiative of Miss Armitage, daughter of the Dr. Armitage already referred to. This Council, Dr. Moorhead continued, was endeavouring to organize blind welfare work throughout the entire country. Already it had started four county branches—in South Tipperary, Waterford, Kilkenny, and Clare—and it was hoped before long to have a branch in every county in Ireland. In Dublin a home visitor had been appointed, and a group of voluntary lady visitors had been secured. A scheme for providing wireless for the blind had been inaugurated, entertainments organized, and the sale of goods had been helped—in fact, every branch of blind welfare work was being undertaken. But the Council required further support if it was to continue its work. Many people had given up subscribing to hospitals since the sweepstakes started. This was a mistake; the hospitals still required financial support, and, above all, the interest of the public in their work. To those, however, who had determined not to subscribe to the hospitals at present he could recommend this blind welfare work as a genuine and most deserving charity. In conclusion, Dr. Moorhead appealed to the public to support the movement to provide wireless sets for the homes of the blind.

Workmen's Compensation Bill

In the report stage of the Workmen's Compensation Bill (Irish Free State) Sir Edward Coey Bigger, in the Senate, moved the insertion in the Bill of a new section which provided that, where compensation was payable under the Act, the court might direct payment to the medical practitioner, out of that compensation, of such sum as it considered reasonable. The House agreed to consider at the same time an amendment on the same subject, proposed by Mr. Foran, which provided that the medical fees payable should be in addition to the compensation. Sir Edward Coey Bigger said that to leave such an amendment as his out of the Bill was tantamount to saying to the employer and the employed that it was not necessary to pay medical fees at all. Mr. Comyn suggested a compromise on the amendment, which would provide that out of the compensation any sum not exceeding £5 would be payable to the medical practitioner, and for any sum exceeding this figure the medical practitioner would stand in the same position as other creditors in reference to the balance of his claims. Mr. Foran contended that the employer should pay for medical attendance; he agreed with Sir Edward Coey Bigger provided the workman was assured of his full compensation. Mr. Lemass, Minister for Industry and Commerce, said that, on a former occasion when the matter was discussed, he was against special provision being made for doctors' fees. Since then he had met a deputation of the Medical Association, which had told him that it was not the practice of doctors to recover fees by law, and that where the fees were due in respect of workmen's accidents there was failure to secure payment in over 99 per cent. of the cases. They could adopt the course either of paying whatever fees the court deemed reasonable, or—as Sir Edward Coey Bigger suggested—of deducting fees from the compensation. Whichever course was adopted there was not likely to be a reduction in doctors' fees; these were more likely to go up. Individual doctors would play fair, but they had to base their legislation on the assumption that

original sin still operated in humanity. He would propose, therefore, that a section be enacted which would provide payment by the employer of doctors' fees, due by the workmen for treatment, to the maximum of £5. without depriving the doctor of his right to recover the balance from the workman. The amendments were, by leave, withdrawn, and permission was given to the Minister to introduce a new section on the lines suggested next week.

Local Services (Temporary Economies) Bill No. 2

At a recent meeting of the medical practitioners in South Tipperary the Local Services (Temporary Economies) Bill, No. 2, 1933, was discussed so far as it affected medical practitioners in the employment of local authorities. The meeting protested strongly against the proposed reductions, and stated that: (1) the work thrown on Poor Law medical officers as the result of the abuse of the term "poor person" to meet the economic depression had increased threefold; (2) private practice had decreased as a result of this abuse and the economic depression more than 50 per cent.; (3) Poor Law medical officers were on duty the entire twenty-four hours of the day, and had to deal with emergency calls at all hours of the day and night; (4) costs incidental to the discharge of the duties of their offices, such as road and petrol taxes, and compulsory insurance under the Traffic Act, had increased considerably, and all of them had to be found out of an already inadequate salary. The meeting also considered a proposed scale of fees forwarded to Health Boards by the Department of Local Government and Public Health, and all the members present pledged themselves not to accept less than £1 1s. for the administration of an anaesthetic. At a recent meeting of County Galway medical practitioners holding offices under local authorities the circular letter received from the secretaries of the Irish Medical Committee was considered clause by clause. Proposals in the circular letter were approved, and Drs. M. G. O'Malley and T. B. Costello were appointed to attend the meeting of delegates to be held in Dublin on a date not yet fixed. Deputy delegates were also appointed.

England and Wales

New Middlesex County Mental Hospital

The first section of what is claimed to be, in design, furnishing, and scientific provision, the most up-to-date mental hospital in the country was opened to patients on February 5th at Shenley, near Radlett, in Hertfordshire. It is the new mental hospital provided by the Middlesex County Council, and has been in process of building since the middle of 1931 on an estate, much of it wooded, covering 500 acres. The entire scheme provides for a mental hospital to accommodate 2,000 patients, with the necessary staff, and the first section now opened has room for 1,046 patients, and also comprises the whole of the administrative offices, as well as a hospital for bed cases, pathological laboratory, x-ray department, operating theatre, dental clinic, dispensary, and provision for light and other treatment. The hospital buildings are on a twin plan about a central axis line, with one side for male and the other for female patients. The villa system has been followed in the design, and numbers of small villas have been erected, approximating as far as possible in their furnishing to home conditions. All the buildings face south, and there are large verandas which can be used by the patients for rest by day or night when conditions are favourable. A feature is to be made of occupational therapy. The estate includes a farm where many men may be congenially employed,

and for others there is provision for handicrafts, including weaving, rug-making, leather work, simple joinery, printing and bookbinding, and basket and brush-making. The kitchen, laundry, and sewing departments will provide occupation for the women. A large recreation hall has been built to accommodate 1,000 persons, and fully equipped for stage productions, concerts, and talking pictures. Cricket and football fields and tennis courts have been reserved in the grounds. The kitchen is of such dimensions as to permit of cooking for 2,500 people daily. With regard to services, the institution is as far as possible self-contained. Water is pumped from a well on the estate into storage reservoirs, and underground conduits distribute the steam heating, domestic hot water, and electrical, telephone, and wireless services throughout the hospital. A number of press representatives and other guests were received at the hospital two days before the informal opening, when Sir William Lobjoit, chairman of the Mental Hospitals Committee of the Middlesex County Council, spoke of what the institution was intended to achieve. It was emphasized that provision was made for the treatment of voluntary and temporary patients suffering from mental breakdown, who can leave on recovery without the stigma of ever having been certified. The medical superintendent at Shenley, Dr. G. W. Shore, with the standing subcommittee of the hospital, is to be congratulated on the work so far accomplished. The total cost of the project will be over half a million pounds.

Darlington Health Services

The staff of the health office at Darlington met on January 23rd to say farewell to Dr. Andrew McFarlane, who recently resigned on his appointment as medical officer to the Scottish Board of Health. The presentation took the form of an easy chair. Expressions of appreciation of Dr. McFarlane's four years' service with the department were voiced by Dr. Dawson, the new medical officer of health, representatives of the sanitary inspectors, health visitors, and clerical staff. Miss Flora Kinnear, matron of the fever hospital, on behalf of the staff presented to Dr. and Mrs. McFarlane a travelling rug and cutlery as a souvenir of their happy relations. The co-ordination of the health services in Darlington is now completed with the following appointments: Dr. G. A. Dawson, medical officer of health, school medical officer, and medical officer to the Public Assistance Committee; Dr. W. L. Hartston, deputy medical officer of health and venereal diseases medical officer; Dr. Isobel C. Brown, assistant medical officer for schools and toddlers; Dr. Elizabeth S. Walker, maternity and child welfare medical officer and public vaccinator; Dr. J. H. Weir, assistant medical officer for tuberculosis and public assistance; Mr. J. L. Liddell, L.D.S., dental officer for corporation health services. The recent purchase of the general hospital by the Corporation has advanced the co-ordination scheme, and it is hoped that the services will be under one roof in the course of the next six months.

Science and Pure Water

The annual report of the Water Pollution Research Board, issued by the Department of Scientific and Industrial Research,¹ draws attention to the fact that although the water supplies of the country are in general much safer than those of some years ago, largely as a result of systematic research and the application of scientific methods, the need for even greater vigilance is occasionally emphasized by outbreaks of water-borne disease. The enteric fever outbreaks at Malton and Denby Dale are cases in point. The report also refers to the outbreak of paratyphoid at Epping in 1931, which, without the constant and careful watch maintained by the Metropolitan

¹ H.M. Stationery Office. (1s. net.)

Water Board, might have spread rapidly, and become extremely serious. The troubles at Maltton, Denby Dale, and Epping emphasize the importance of preventing, as far as possible, the pollution of our rivers and other sources of water supply. In many cases, however, the condition of rivers cannot be improved to the necessary extent until satisfactory methods of reducing the quantities or improving the composition of various domestic and trade effluents have been devised. In view of the importance in many industrial processes of adequate supplies of soft water, and of the fact that several water supply authorities are softening their water before it reaches the consumer, investigations are being carried out on the base-exchange process of water softening. Other important work in progress deals with the contamination of water by lead. A survey of the existing knowledge of the subject will shortly be published, and will include sections dealing with the lead content of drinking-water, difficulties of diagnosis of lead poisoning from water, protection of consumers, the action of water on lead, electrolytic action, etc. The survey has revealed many divergent and contradictory opinions regarding the effects of various conditions on the plumbo-solvent action of different waters and the amounts of lead which must not be exceeded in drinking-water if risk of poisoning is to be avoided.

Child Guidance Council

Lord Blanesborough took the chair at the annual general meeting of this council, held at the Westminster Palace Rooms on January 22nd. He paid tribute in his address to the generosity of the Commonwealth Fund and of Mr. Harkness, who had not only enabled the movement to be started in this country but, notwithstanding the stringency of financial conditions in America, had never diminished their bounty. Lady Snowden said that she hoped to see a child guidance unit attached to every school or small group of schools in the country. Dr. William Moodie, in an admirable exposition of the methods and aims of the council, said that during its five years of work the general public antagonism to it had largely given place to sympathy, curiosity, and understanding. Clinics had been opened in many centres; each was staffed by a three-specialist team—a psychiatrist in charge, assisted by an educational psychologist and a social worker. Training clinic workers was an important part of the council's activities, for a high level of special competence was necessary. Problems were approached on a practical level, and the findings and reports were couched in simple language. The clinic rarely advised parents; it stated the child's problem, and the parent usually co-operated willingly. A representative of the Home Office testified to the great interest which the Government took in the work and the unexpected enthusiasm of education authorities all over the country in questions affecting child welfare. The council would do invaluable service in assisting the new juvenile courts set up under the Children and Young Persons Act, 1933.

The Marriage Bar

The standing order of the London County Council whereby women employees have to resign their posts on marriage has been suspended in the case of a woman medical officer who has been engaged for the last two years at the central pathological laboratory of the Mental Hospital Department. It is stated that the research which she has been undertaking, on the functioning of the nervous system, has so far had encouraging results, but will not be completed before the end of five more years, and that it will be interfered with gravely if her services are terminated. Accordingly she has been retained for as long as may be necessary up to the end of 1938.

Reports of Societies

RESPIRATION

At a meeting of the Anaesthetics Section of the Royal Society of Medicine, on February 3rd, with the president, Dr. H. P. FAIRLIE, in the chair, a discussion took place on respiration.

Professor SAMSON WRIGHT, dealing with normal breathing, discussed first the situation of the respiratory centre, concluding that it was unnecessary to postulate a series of centres controlling each other from above downwards. One "centre" acting normally as a co-ordinated unit, he held, would explain the fact that when parts of it were cut off the portion left could no longer control breathing normally. Continuing, Professor Wright mentioned the inherent rhythmical activity of the centre, and described the mechanical regulation of the depth of breathing. He then gave a brief outline of the purposes served by breathing as an approach to the subject of its regulation. Pulmonary ventilation, other things being equal, was proportional to the metabolic rate, and it also varied with the reaction of the blood. Breathing was also influenced by the heat-regulating mechanism of the body and by the level of the arterial blood pressure. Oxygen lack, if severe, also stimulated respiration in certain circumstances. Professor Wright then discussed the part played by carbon dioxide in the regulation of breathing, mentioning the effects of excess and of diminished amounts of this gas in the blood. Changes in the hydrogen-ion concentration of the blood due to causes other than increased carbon dioxide formation in the tissues also affected the centre. Oxygen lack, said Professor Wright, had a complex effect upon breathing. When abrupt and excessive, diminished oxygen intake produced rapid failure in respiration. If less severe some increase in breathing might occur, but compensation in this way was unsatisfactory. Usually an increased rate rather than an increased depth of respiration occurred from oxygen lack. Professor Wright pointed out that, while oxygen lack directly depressed the isolated respiratory centre, it stimulated breathing reflexly through the sensory nerve endings in the carotid sinus and aortic arch. Finally, the speaker referred to the part played by the vagi in the regulation of respiratory rhythm, describing how distension of the lungs produced a reflex expiration.

Dr. ALAN MONCRIEFF, discussing failure of respiration, mentioned first the occurrence of this in the newborn, and urged that anaesthetists were especially well qualified to help in resuscitation of the infant from their experience with intratracheal intubation. He said that respiratory failure at this age period was caused by obstruction in the respiratory tract, delayed expansion of the lungs, narcosis, failure of circulation, intracranial damage, and failure or delay in the function of the respiratory centre. He discussed the use of a combined suction and air-delivery unit to deal with failure due to the first two causes on this list, stressing the value of inhalations of 5 per cent. carbon dioxide in oxygen to stimulate the respiratory centre. Dr. Moncrieff then set out a classification of respiratory failure in general, and referred first to some of the causes of central failure, due mainly to impaired nutrition and poisoning of the controlling nervous mechanism. Under the heading of peripheral failure the speaker described first the mechanical effects of a reduction in vital capacity, pointing out, however, that this alone did not necessarily indicate the degree of failure of the lungs as ventilating organs, since there was a large degree of reserve available. Hence, he said, the need for studying the efficiency of pulmonary ventilation. Some help could be obtained, continued Dr. Moncrieff, from a consideration of the ventilation in relation to oxygen intake, but of more importance was a study of the exact amount of air actually reaching the alveoli. This involved a consideration of the so-called "dead space," and it was shown that efficient ventilation obtained when this was kept to as small a proportion of the tidal air as possible. The speaker then mentioned the importance of the integrity of the alveolar epithelium and of the

circulation through the lungs. Finally, discussing the treatment of respiratory failure, he laid stress on the importance of carbon dioxide in oxygen, and said that tracheal intubation or the use of a mask was preferable to any other form of artificial respiration as a measure of resuscitation.

The PRESIDENT inquired about the normal reaction to breathing carbon dioxide, as to what concentrations and what length of time were required before distress arose. Dr. C. A. KEELE pointed out that in the treatment of respiratory failure drugs would be likely to fail, as carbon dioxide failed, if the circulation was not able to carry them to the centre. Dr. J. GUOSI mentioned the effect on breathing of paralysis of the respiratory muscles as might occur in spinal anaesthesia. He asked if this affected the working of the respiratory centre, and also what was the effect upon central control of an open thorax. Dr. J. D. RUSSELL asked why, if artificial respiration might have had effects by the washing out of carbon dioxide, the Drinker apparatus, which produced such efficient ventilation, was advocated. Dr. E. FLETCHER gave an account of cases of respiratory failure due to filling of the lungs with lipidol. He wondered why the accumulation of carbon dioxide in the blood in such cases did not stimulate the respiratory centre. In investigating early disease of the respiratory organs, such as bronchitis without any infiltration of the pulmonary tissue, he had found a striking decrease in the reserve air. Dr. R. J. MINNITT referred to some experiments he had made in which there was a fall in the carbon dioxide content of the venous blood during anaesthesia, except where this gas had been inhaled at some time during the experiment. Dr. W. HOWARD JONES mentioned the effects of prolonged restriction of oxygen intake during the administration of nitrous oxide.

TREATMENT OF OTITIS MEDIA

At a meeting of the Section of Otology of the Royal Society of Medicine on February 2nd, with Dr. W. J. HARRISON presiding, a discussion took place on the treatment of chronic catarrhal otitis media (excluding otosclerosis) and of deafness and dry suppurative otitis media.

Mr. W. M. MOLLISON said that the treatment of chronic catarrhal otitis media was, even in these days, a poor thing. The name of the condition had a gloomy sound, and the prognosis was gloomy—a few kind words to the patient, and advice about some sort of aid. Dry suppurative otitis media was a contradiction in terms; it related to a condition remaining in the middle ear when suppuration had been brought to an end. Early treatment of all ear infections was the only efficient method of preventing subsequent deafness. Sir William Milligan had been accustomed to claim that correct treatment of the acute ear condition should always result in normal hearing; the lesson was at last being learned, and there was less deafness as a result of acute middle-ear suppuration than formerly. The non-suppurative cases were a real difficulty. From the point of view of deafness it was better to have a suppurating ear than a catarrhal one. Aurists knew what considerable degrees of deafness in children escaped the notice of parents and teachers. Once established in children, a catarrhal otitis media led to increasing deafness, compensated for in early years, but becoming worse with time. Mr. Mollison had noticed this among persons of 20 or 30, who stated that they were experiencing much deafness, though there had been nothing immediately to account for it, and, on going back into their history, some trouble of this kind in childhood was elicited. The speaker quoted from the writings of James Hunter, sixty years ago, on missed diagnosis and ineffective treatment, and said that apart from the recognition of adenoids and sinus infection there had been little progress since Hunter's day. Asking whether exudative otitis media ever passed the antrum and mastoid cells as in suppurative cases, Mr. Mollison described a case under his care which suggested this possibility. He did not know when acute catarrhal otitis media became chronic; physicians found some mystic

significance in a period of three months, but he did not think aurists would fix arbitrary time limits. In children one need not despair of the recovery of hearing even after long periods of the acute condition. Sources of infection must be removed from both nasopharynx and sinuses. In adults inflation was not always easy, but the passage of the bougie was often helpful. Various fluids and gases had been recommended for blowing through the catheter—iodine vapours, hot air, and the like. Local treatment of the membrane might be attempted, and vibratory massage had its vogue. Ionization was reported to have been helpful, but he could not speak from experience; nor could he speak of the Zünd-Burguet electrophonoid method. [Six cases illustrating alleviation of deafness and tinnitus by this method had been shown earlier in the meeting by Dr. GEORGE CATHCART.]

Mr. C. P. WILSON said that Mr. Mollison had put forward the orthodox views as to treatment of this condition. Unfortunately, progress in this field had been very slow. The treatment of any condition, unless it was to be purely empirical, must be founded on a true appreciation of the underlying pathology, and the ideas of pathology current were those which had been accepted from the old teachers almost without question. A good deaf was heard of atrophy of the tympanic membrane, and so forth. The only cases he had seen pathologically where it might be expected to find atrophic changes had all shown the presence of otosclerosis. It was his firm opinion that the cases of old catarrhal deafness with atrophic changes of the tympanic membrane had also the otosclerotic condition, and when a case had reached that stage he knew of no really effective treatment; furthermore, any active local measures were more likely than not to increase the rate of progress of the disease. The treatment of these cases was purely educative, and designed to improve hearing from the social point of view. With regard to earlier cases of catarrhal deafness he suggested that the anatomy of the Eustachian tube was a factor of much more importance than was usually considered. The normal tube was long and narrow, but a small percentage of persons had a short, relatively wide tube, and these were more vulnerable to the spread of infection from the nasopharynx. People with Eustachian tubes of this type often had attacks of mild subacute catarrh, with very little associated pain, but the recurring attacks of mild infection might leave them with an infiltration of the mucosa of the middle ear, leading to fibrosis and contraction, and an indrawing of the tympanic membrane, or might result in the general onset or acceleration of an otosclerotic process, with atrophy and degeneration of the mucosa of the middle ear. Lately it had been said that the deafness in these cases was due to thickening of the mucosa around the stapes, and this condition had been allied with otosclerosis. This again was a theory without any definite pathological foundation. Treatment in these cases must never be local; manipulative treatment could not be of any use, and might increase the fibrosis. Where an otosclerotic element was present the treatment should be preventive, and directed to the nasopharynx and pharynx. Adenoids were a common cause of trouble. The removal of tonsils, in the presence of a chronic infection of the nose, did more harm than good. If the tonsils were removed and the nasal infection persisted there was always an increase of lymphoid tissue on the wall of the nasopharynx. The nasal infection must be cleared up first. If the tonsils were so infected as to be incapable of recovery they might be removed later, but on no account should the tonsils be removed until the nasopharynx was tackled. If Eustachian catheterization showed the tube to be clear, or if on section no fluid could be drawn from the ear, then local treatment must be stopped. Patients with long, narrow Eustachian tubes had fewer attacks of infection from the nasopharynx, but the attacks they did get were associated with Eustachian obstruction. These people were the subjects of catarrhal infection plus Eustachian obstruction, and it was in this group only that, he thought, local treatment was of any value. Mr. Wilson added that otosclerosis was a much more common complication of chronic catarrhal deafness than was usually realized. Catheterization should

be undertaken only if definite improvement in the hearing was achieved. For these cases he regarded the Politzer method of inflation as unsound and unsafe.

Dr. ALBERT GRAY said that adhesions might occur in an early stage after an acute or subacute middle-ear inflammation which had proceeded to suppuration; the most common sites for these adhesions were the head of the malleus and the body of the incus. Adhesions might also occur after a drying up of chronic middle-ear suppuration; sometimes these bound down the remains of the tympanic membrane to the promontory. In another condition newly formed fibrous tissue might be found in the middle ear without any preceding inflammation or exudation. In this there was a very slow increase in the connective tissue in the muco-periosteum of the middle ear.

Mr. LOWNDES YATES spoke of a method of aspiration which he had found useful in the kind of cases under discussion—the displacement of 3 c.cm. of liquid paraffin, with the patient in the recumbent posture. It was not always good practice to inflate the ear, especially if the Eustachian tube contained pus, as this might be blown up into the ear. Mr. THACKER NEVILLE said that anything which dilated the blood vessels of the inner ear in chronic catarrhal deafness seemed to help. A rheumatic patient who had histamine treatment found that her hearing was improved by it, and demanded it for her deafness. The speaker used diathermy as a routine in all his cases of catarrhal deafness. Spa treatment for these ear conditions was more neglected in England than in other countries.

Dr. A. R. FRIEL said that Eustachian obstruction and catarrhal otitis media in children were usually accompanied or preceded by rhinitis. Any treatment which was effective for the rhinitis was a preventive or curative agent for the ear condition. Such a treatment was devised by Gautier of Paris, and was called diastolization. It consisted in the introduction of soft rubber hollow bougies along the floor of the nose into the space between the inferior turbinal and the septum. This mild stimulus caused contraction of the blood vessels in the turbinal, and the latter shrank, and so the passage became open. With the recovery of this part the Eustachian congestion also subsided. The speaker had also found useful a weak solution of nitrate of silver, applied by Yankauer's applicators. To restore the position of the drum membrane, as well as to open the Eustachian tube, politizerization was employed. Mr. T. B. LAYTON said that for many years it had been the custom to consider the changes in the middle ear as the physical basis of deafness, and the changes in and around the mastoid antrum had received scant notice. The mastoid bone was part of the muscular system of the body, and was the remote part of a diverticulum, and Mr. Mollison had taught him that if a person with otitis media and some suppuration had undue deafness it was certain that that infection had spread into the mastoid or its associated cells.

Mr. E. WATSON-WILLIAMS stressed the great variations met with in tympanic membranes, and how little the appearance and condition of the tympanic membrane were correlated with the degree of deafness. In his experience the condition of the tympanic membrane was as often misleading as it was helpful in putting one on to the cause of deafness in a particular case. He had seen a number of cases with marked degeneration of mucous membrane associated often with chronic degeneration of the nasopharyngeal and nasal mucous membrane, and he thought many of these patients were subjects of iodine deficiency. Mr. HAROLD KISCH remarked that one was often faced with the problem whether submucous resection or other operation ought to be performed to help cases of chronic deafness. A useful step towards that decision was to test the hearing before doing any manipulation, and then to spray the nose with a solution of cocaine and adrenaline. In a proportion of cases the hearing was improved by this procedure, and in these he found operation was of use. Mr. J. F. O'MALLEY thought that a better understanding of the physiology of air movements in the middle-ear cavity was needed, because all the lines of treatment had a bearing on alteration of the air pressure in the middle ear.

IMMUNIZATION AGAINST YELLOW FEVER

At a meeting of the Royal Society of Tropical Medicine and Hygiene on January 18th, with the president, Sir LEONARD ROGERS, in the chair, Dr. G. W. M. FINDLAY read a paper on immunization against yellow fever.

Dr. Findlay said that rapidity of travel had been greatly increased by the application of the internal combustion engine to transport on land and in the air. As a result, a further extension of the areas infected with yellow fever was within the bounds of possibility, since many countries which already harboured the mosquito vector of yellow fever could now be reached by a traveller from an endemic focus well within the incubation period of the disease. Some method not merely of controlling but of eradicating yellow fever was thus of the greatest importance. Such eradication could be brought about only by destruction of either the vector or the virus, and since the vast areas in Africa and South America now known to be infected with yellow fever rendered it impossible to annihilate the mosquito vector, a practical method of immunization would be of inestimable value. Although Carlos Juan Finlay suggested the possibility of immunizing against yellow fever forty years ago, no safe or efficient means of employing the ordinary virus of yellow fever could be found. In 1930, however, Max Theiler made the important discovery that yellow fever could be transmitted to mice by intracerebral inoculation. Mice thus inoculated did not develop viscerotropic lesions similar to those found in rhesus monkeys and man, but died from an encephalitis. Intraperitoneal inoculation was only fatal in young mice, in which the virus rapidly became localized in the central nervous system. After serial passage the virus lost its power to produce viscerotropic lesions in monkeys, though when inoculated intracerebrally it produced an encephalitis in all species of monkey. So far as monkeys and rodents were concerned all efforts to reconvert the fixed neurotropic virus into the viscerotropic strain had failed. The use of this neurotropic fixed virus for immunization removed many of the difficulties arising from the ordinary viscerotropic strain, more especially when human yellow fever immune serum was also injected. In their original experiments Sawyer, Kitchen, and Lloyd (1932) immunized fifteen persons by a single injection of a dried mixture of living yellow fever virus, fixed for mice, and human immune serum with separate injections of enough additional serum to prevent detection of virus in the peripheral blood stream. One person was similarly immunized by injecting immune serum and dried virus separately.

In this country up to the end of 1933, continued Dr. Findlay, 200 persons (152 men and 48 women) were immunized by injections of neurotropic mouse-fixed yellow fever virus and human yellow fever immune serum. Those immunized included civil and military officials, medical officers, and nursing sisters of the West African Medical Service, missionaries, traders, and wives of officials proceeding to the West Coast, as well as laboratory workers. They were divided into three groups, according to the relative amounts of immune serum and virus injected. Group I (forty persons) was inoculated subcutaneously in the abdomen with from 0.3 to 0.5 c.cm. of human immune yellow fever serum per kilogram of body weight, followed four to six hours later by from 0.25 to 0.5 c.cm. of a 10 per cent. suspension of virus in normal human serum injected subcutaneously in the arm. Twenty-five (62.5 per cent.) of those inoculated by this method developed febrile reactions with a rise of temperature above 99° F. Group II (110 persons) was inoculated intradermally in the abdomen with 1 c.cm. of human immune yellow fever serum, followed two hours later by from 0.1 to 0.5 c.cm. of 10 per cent. suspension of virus injected into the same area. Forty-six (41.8 per cent.) of those thus inoculated developed febrile reactions. Group III (fifty persons) was inoculated intradermally with 1 c.cm. of human immune yellow fever serum, followed two hours later by intradermal injection of from 0.00625 to 0.05 c.cm. of 10 per cent. virus, together with the subcutaneous injection of 5 c.cm. of human immune yellow fever serum. Fifteen (30 per cent.) of those thus inoculated developed febrile reactions. The reactions consisted for the most

part of headache, aching in the limbs and back lasting for from twenty-four to forty-eight hours, accompanied by a leucopenia and slight bradycardia. In no case did there develop any encephalitis or "paralytic accident," and in only a very small number was the reaction severe.

The sera of 115 persons were examined for the development of immune bodies after immunization. Immune bodies began to appear in the blood stream seven to eight days after inoculation, and attained their maximum titre in from three to four weeks. Ten to eleven months after immunization the immune body titre decreased, but protective immune bodies could still be detected up to at least sixteen months after inoculation, and probably for much longer periods. So far the complete success of immunization against yellow fever had only been demonstrated in laboratory workers, for among these since the introduction of prophylactic immunization there had been a complete absence of the accidental infections which were at one period so common.

Colonel S. P. JAMES said that the complete cessation of laboratory accidents after inoculation by this method constituted definite proof of its efficacy, and it could now be regarded as a sure prophylactic measure for all colonial officers and others going to endemic zones of yellow fever. In aeroplane traffic the real practical risk was limited to human cases incubating the disease, and this danger could now be eliminated by the inoculation of the personnel of aircraft and all intending passengers. Colonel James then demonstrated by means of a spot map that there were great areas in a continent like Africa where the people possessed immunity to yellow fever, though clinical yellow fever had not been reported there. Such areas had been designated "silent" regions by Dr. Sawyer; the speaker suggested that in yellow fever, as in small-pox, non-virulent strains existed which caused little illness, but immunized against the virulent type of virus.

Dr. HAMILTON FAIRLEY said that unfortunately personal experience had made him realize the importance of the new prophylactic inoculation introduced by the Rockefeller workers, as some little time ago two of his own laboratory staff had contracted yellow fever during haematological and biochemical examinations, and one had died. Skin abrasions were absent, and evidently infection had resulted from contact with microscopic quantities of blood. In the past doctors and nurses must have contracted this disease when taking routine blood smears from febrile cases during the first two or three days of yellow fever, or even during the incubation period, and in endemic areas gloves should be worn whenever blood was being collected. In addition, prophylactic inoculation would now be available for both medical and nursing staff.

Dr. CARMICHAEL LOW stated that in the West Indies in the old days during an epidemic mild cases of fever and albuminuria did occur, and had a protection test been available it would undoubtedly have shown them to be yellow fever; variations in the severity of cases were due to variation in individual resistance. Dr. Findlay had said that the experiments of Stokes, Bauer, and Hudson demonstrated the ultra-microscopic nature of the virus; this he did not think quite fair to the early American commission, as it had shown the virus was a filter-passer.

Dr. MANSON-BAHR inquired whether the virus of yellow fever had any power of stimulating latent malaria, and, if so, might it not be used as a test to reveal latent infection? He asked also whether the virus of yellow fever might not eradicate filarial infection; he had seen two cases in which embryos had disappeared after an attack of yellow fever. Dr. R. A. O'BRIEN said that natives of West Africa appeared to possess some natural immunity, since the disease in them was generally mild and difficult to diagnose, whereas in Europeans it was typical and generally fatal: he had, however, seen epidemics in which the mortality was as high among natives as among Europeans. Dr. FELIX mentioned certain similarities between typhus and yellow fever. Killed typhus virus as it existed in some fluids of the body and blood was incapable of producing any immunity, but killed virus obtained from blood-sucking insects, such as the louse and red flea, was quite different, since it could produce active immunity. He wondered if

the killed yellow fever virus from the mosquito would immunize.

Dr. FINDLAY pointed out, in reply, that while the American commission had shown the virus of yellow fever to be filterable, it had not proved it to be ultra-microscopic. The terms were not synonymous: suspension of certain spirochaetes, for example, gave filtrates which were infective.

CORRESPONDENCE

The Tuberculosis Problem

SIR,—I have read with interest the illuminating letter by "A. R. F." under the above title in your issue of February 3rd. He is perfectly right when he says: "Can any tuberculosis clinic afford to spurn the use of (a) repeated sputum examinations, (b) an x-ray apparatus, (c) careful and repeated clinical examination, and (d) tuberculin, especially in the case of children, as aids to early diagnosis?"

I thoroughly agree with what he says about the tuberculosis clinic. The following recommendations to bring about the improvement, which is rightly held by "A. R. F." to be so necessary, were made by the Tuberculosis Group of the Society of Medical Officers of Health:

"The efficiency of the Tuberculosis Service varies widely in different districts, but backward areas are being improved by wise stimulation from headquarters. This supervision should not be used so as to hamper individual initiative, or impede experimental methods."

"The chief factor in success is the personality and ability of tuberculosis officers and superintendents of sanatoriums, and to secure this, remuneration sufficient to attract good men is all-important. An indifferent officer fails to obtain the confidence and esteem of the general practitioners, on whom so much depends. It is better to have fewer and better paid officers with larger areas than a large number of poorly paid men of mediocre capacity."

"Rural areas of 250,000 population and urban areas of 350,000 can be managed by one whole-time officer with adequate medical and clerical assistance, and would provide sufficient remuneration. The service should be graded so that those who had acted as assistants might become higher salaried whole-time consultant tuberculosis officers or senior sanatorium superintendents. Superannuation schemes should be generally adopted or so arranged that an officer does not lose by transference to another district."

"The tuberculosis officer and sanatorium superintendent should have at their disposal facilities for diagnosis, such as an x-ray outfit, and for special forms of treatment, such as light and artificial pneumothorax. Each tuberculosis officer should have hospital beds."

"Dispensary and sanatorium officers should be first and foremost clinicians, but should have a public health outlook. Facilities to attend post-graduate courses are of the highest importance. In certain circumstances it may be advantageous for the medical superintendent of a sanatorium to be responsible for clinical work in the vicinity of his institution."

"The practitioners' sense of responsibility in the prevention and treatment of tuberculosis must in no way be impaired, and it is the first duty of dispensary and sanatorium officers to ensure this. One of the most helpful qualifications for these officers is to have been themselves in private practice."

With regard to the second suggestion in the letter, "Is there any system of inspection of such organizations, and is any attempt made to keep them well equipped and to standardize their functions?" it is to be regretted that the Ministry of Health are still withholding the publication annually of Memorandum 131/T (analysis of work done during the year under the schemes of local authorities for the treatment of tuberculosis, as shown in the returns furnished in accordance with Memorandum 37/T).

—I am, etc.,

G. LISSANT COX,

Preston, Feb. 5th. Central Tuberculosis Officer, Lancashire County Council.

Artificial Pneumothorax for Tuberculous Children

SIR,—In view of the acknowledged comparative rarity of pulmonary tuberculosis of the *adult* type in children, the large number of cases (132) reported by Dr. Reade in the *Journal* of February 3rd (p. 214), as having been treated by him at High Wood Hospital by artificial pneumothorax since 1926, invites some questions.

1. On what evidence was the diagnosis of pulmonary tuberculosis based?

2. In what percentage of cases were tubercle bacilli found in the discharges?

3. Assuming bacilli were not discovered in many of the cases, having regard to the excellent outlook for the great majority of children with *primary* infection, in the absence of interference of any kind, what advantage does Dr. Reade claim for collapse therapy in this particular group?

All three children whose cases I reported in the *Journal* of January 6th, as undergoing artificial pneumothorax treatment, had tubercle bacilli in the sputum. There was nothing very remarkable about any of them, except perhaps the fact that together they happened to be in hospital about the same time. Many tuberculosis physicians must have treated similar cases in children, from time to time, on much the same lines.

Dr. Jessel (consultant tuberculosis officer, Lancashire County Council) reported in the *Lancet* of December 16th, 1933, the case of a boy, aged 8 years, with tubercle bacilli in the sputum, whose cavity he had closed by artificial pneumothorax. Dr. Macdonald of Battersea Tuberculosis Dispensary tells me that he is at present treating by the same means a girl, aged 5, with a positive sputum. But there must be few practitioners who have had experience of such a number of cases in children as Dr. Reade mentions in his letter. Perhaps, some time, he will be good enough to publish full details in another communication.—I am, etc.,

Oxford, Feb. 4th.

WILLIAM STOBIE.

Otitis Media

SIR,—I have read with interest Dr. Douglas Guthrie's paper on the "acute ear" in your issue of January 6th. I like the comparison of the "acute ear" with the "acute abdomen" if only for the emphasis which it gives. The acute abdomen, however, is becoming less common. I can go months now without seeing one, but acute and chronic ears are as abundant as ever. So far as I know, none of the school medical officers or the Ministry of Health has drawn public attention to the prevalence and devastating effects of otitis media. Hardly a day passes but I see a new case or the active recurrence of an old one. It seems to be quite common for an old otitis media to have periodic outbursts practically throughout life. In addition to the cases of frank otorrhoea one sees many cases of earache which, as the result of treatment or of superior resistance, proceed no further.

The treatment of both the acute and the chronic ear is not very satisfactory as far as methods applicable in the home go. I have notes of a good many, all of which I have tried without being able to feel that one is better than another, or that there has been any real advance in the last thirty years.

In the acute case I have never incised the drum and have never seen it done. I worked for some fifteen years for other doctors. None of them ever did it, and most of them admitted they had never done it. Yet I am sure otologists would not advocate early incision unless

they believed that it would go a long way to reduce the number of chronic ears and of serious complications. The trouble about incising the drum is the need for a general anaesthetic. The general practitioner avoids it owing to lack of time and the necessity of finding a colleague to be present or give the anaesthetic. The public, at least in their own homes, are not prepared to consent to a general anaesthetic for what they regard as a trivial condition.

Is it not possible for the otologist to find out a means of doing the operation under local anaesthesia of some kind? There is rarely any difficulty in getting a good view of the drum in children, provided one goes about the business with patience and care, and I imagine the further step of incising the drum could be done without the child being aware of it, provided he felt no pain. The objection used to be made, and may still be made, that local anaesthetics are not very effectual in suppurative conditions. It may be true in the case of the drum, but it is certainly not true for suppurating fingers and breasts, both of which I operate on frequently under novocain infiltration without causing any pain whatever.

I plead guilty to inflicting a long letter upon you, Sir, but the subject is very important and deserves wide consideration.—I am, etc.,

Edinburgh, Jan. 31st.

JOHN M. DEWAR.

Mind and Body

SIR,—As medical superintendent of a mental hospital of approximately 1,400 beds, may I be allowed to express my congratulations and thanks to Professor Arthur J. Hall for his paper on "Bodily Diseases in Mental Disorders," published in your issue of January 27th. All his observations are most pertinent, and demonstrate the close relation of mind and body, a subject which I think is impressed upon nurses trained in mental hospitals more than is done in those trained in other hospitals. Any physical illness, no matter how slight, has its mental accompaniment, just as most mental states have their physical counterparts.

Professor Hall's article will do much to point out to our confreres in the profession the difficulties we have to contend with in the psychiatric field of work, and in my opinion he deserves the thanks of all so occupied. I hope all interested in mental hospital work will read and preserve the same.—I am, etc.,

RICHARD EAGER, O.B.E., M.D.

Devon Mental Hospital, Exminster, Feb. 5th.

Some Factors which Regulate the Uterus

SIR,—Interesting though the remarks of your annotator in the *British Medical Journal* of January 6th, and subsequently those of Mr. Jeffcoate in a letter on January 20th (p. 122), are, it may be that both writers have ignored certain facts which bear on the activity of the uterus and may be important in the explanation of those factors which determine the onset of parturition.

To Reynolds, I think, belongs the credit of showing that the administration of oestrin to the living animal is followed, within a comparatively short latent period, by increased uterine contractions. Now it must be remembered that such an effect is not necessarily due to a direct action upon the uterine muscle in the same way as, for example, histamine might act when administered, but may depend upon any of the following mechanisms: (1) the substance may indeed directly act upon the muscle fibres and bring about contraction of these; (2) the substance, though having no direct action upon the muscle, may

cause a contraction indirectly—for example, by an alteration of the blood supply; (3) the substance may bring about the liberation or increased production of some other substance in the body, which then in turn causes contraction of the uterine muscle; (4) the substance may bring about alterations in the properties of the uterine muscle which may lead to increased contractions dependent upon changes in the intrinsic contractile mechanism; (5) the substance may exert such an action upon the uterine muscle that it will become excitable to other substances which are otherwise ineffective.

Before we can determine the part which oestrin may play in the control of the physiological uterine activity, especially during gestation and parturition, it is necessary to try to analyse the mechanism through which this activity is exerted. The evidence available is all against the view that oestrin directly stimulates the uterine muscle to contraction. Not only is the latent period of its effects, when administered *in vivo*, too long to support such a hypothesis, but the direct *in vitro* investigations (Marrian and Newton, 1932) also afford strong evidence against it. On the whole, we can definitely dismiss this as a possible important factor in parturition. The possibility that oestrin may influence uterine activity through an effect in the blood supply, too, has not as yet been investigated, though Barcroft and his co-workers (1933) have shown that certain very interesting alterations in the vascularity and metabolism of the uterus and its contents take place during gestation. The possible relation of these changes to the activity of the sex hormone may prove a fruitful field for investigation. The view that oestrin causes a stimulation of the posterior lobe of the pituitary was originally put forward by Dixon and Marshall, but their findings have not been substantiated by later investigators. At present the evidence does not warrant the conclusion that this is an effective mechanism in parturition.

We are therefore left with the possibilities that oestrin may influence the uterine activity either by an effect upon the intrinsic mechanism which controls the rhythmic contractions of the organ (and whose nature is unknown) or by acting upon the uterine muscle so as to render it excitable to the action of substances which otherwise have no effect upon the organ. The hormone may, of course, exert both types of effects. Now there is considerable evidence to show that the uterine muscle at parturition attains a certain definite state in regard to its reactivity to oxytocin, and that this state is different from that observed at any other time before or following parturition. Moreover, by the action of oestrin it is possible to induce in the uterine muscle of the non-pregnant animal a state similar to that observed at parturition. These findings, in general, apply not to one particular animal, as so many studies on uterine activity do, but to species as widely separated as man, the rabbit, and the mouse. In all these the state of reactivity of the uterine muscle at parturition can be given in certain very definite terms which are, within the limits of experimental error, exactly the same in all three. In other words, at parturition a concentration of oxytocin of 0.001 to 0.01 unit per 100 c.cm. will cause contraction of the uterine muscle, while considerably larger amounts of that posterior lobe hormone are necessary to give a similar effect during pregnancy and during the puerperium (the latter statement applies only to the rabbit and mouse, the reactivity of the human uterus during puerperium having not yet been accurately studied). Further, the injection of crystalline trihydroxy- or ketohydroxy-oestrin into the ovariectomized rabbit and mouse will bring about such changes in the uterine muscle that it becomes reactive to doses of oxytocin varying from 0.001 to 0.01 unit per 100 c.cm.—that is, *doses exactly similar to those effective at parturition*. It is noteworthy that clinical evidence supports the view that the

uterus attains its greatest reactivity to oxytocin at parturition.

What the factors are which presumably, through the medium of oestrin, control those changes in the reactivity of the uterine muscle which culminate in parturition is at present unknown. That the corpus luteum cannot play, in all animals studied, a determining factor, is definitely established. The possibility that the placenta may secrete a substance having an effect similar to the inhibitory luteal hormone cannot be excluded, nor is it impossible that the gonadotropic hormones may possess such properties. Further studies of these questions are, however, necessary. It is interesting to note, however, that if the uterine contents are removed even during the later stages of gestation then the high reactivity of the muscle to oxytocin characteristic of parturition never develops; on the contrary, large doses of the posterior lobe hormone are necessary to cause contraction of the muscle. This finding suggests that the uterine contents may ultimately play a decisive part in determining those changes in the uterus which culminate in parturition.—I am, etc.,

Edinburgh, Jan. 29th.

J. M. ROBSON.

Infectivity of Scarlet Fever

SIR,—I would like to ask if authorities can ascertain how long the infectivity of the organism of scarlet fever lasts in a case that has clinically cleared up.

A. B. and C. D. were admitted to a convalescent home on October 24th and November 7th, 1933, respectively. They had both had scarlet fever during July and August. There was no evidence of infectivity on admission, though A. B. had one tonsil slightly enlarged, and C. D. had a bad habit of explosive talking into the faces of others. E. F., a delicate little boy with an unhealthy mouth, developed the disease on November 19th. He was afterwards found to be carrying Klebs-Löffler bacilli. G. H. cut his knee, and on December 1st developed a scarlatinal rash. I. J. developed a mild attack on December 16th. As far as possible the contacts were isolated, and there have been no more cases. I have no doubt that C. D. or A. B., or both, were carrying the organism.

Is it the practice in London or elsewhere to undertake throat-swabbing and cultivation of the haemolytic streptococcus in cases convalescent from scarlet fever, as we do in cases of diphtheria for Klebs-Löffler bacilli? Scarlet fever appears to be somewhat prevalent at present, and return cases are not infrequent. Accidents like this much interfere with the work of convalescent homes and schools.—I am, etc.,

HUGH M. RAVEN, M.R.C.S., L.R.C.P.

Broadstairs, Feb. 4th.

The New Cancer Problem

SIR.—Many readers of Mr. Hastings Gifford's letter in the *Journal* of January 20th (p. 121) will find in it a reflection of their own thoughts. In the reports of the Imperial Cancer Research Fund a clinician seeks in vain for help in his own problems at the bedside. Outside this "official" literature, however, there is much which to the physician is both reasonable and practical—for example:

1. Sampson Handley's *Genesis of Cancer*, stressing lymph stasis and proliferation of lymphocytes.

2. Cherry's experiments on mice, also stressing the lymphocyte as an essential link in the production of cancer.

3. Shaw-Mackenzie's theory and practice, built on the deficiencies of pancreatic enzymes in cancer cases.

4. The oft-mentioned familial character of cancer. (Shaw-Mackenzie published an extreme instance where the father was alcoholic and the mother and six of their children died of cancer. I have mentioned in your columns a family where both parents and five of their children died of cancer of the stomach.)

There is a common disease which satisfies all the criteria suggested by the above, and of which only one aspect has so far been studied in any detail. It is a lymphophilic disease of great chronicity, affecting the pancreas and liver in the great majority of cases, the only common truly familial disease, and already clearly implicated as the cause of cancer in certain organs. The causative organism has a life-cycle of which only the active spiral phase has received full attention. The chronic granular phase awaits, and deserves, the close study of research workers who are also clinicians. Is it not time, Mr. Editor, to discard the complacent smile which so often greets the word syphilis?—I am, etc.,

Cardarvon, Jan. 30th. GRIFFITH EVANS, D.M., F.R.C.S.

Colonic Irrigation

SIR,—During a discussion on mucous colitis at the Section of Physical Medicine of the Royal Society of Medicine, reported in the *Journal* of January 27th, several speakers referred to its treatment, at the spas and elsewhere, by colonic irrigation. Dr. Geoffrey Holmes's detailed description of the method employed at Harrogate was greatly appreciated. Neither he nor any of the other speakers raised a point which they—quite rightly—regarded as outside the province of that meeting—namely, the qualifications of those responsible for its administration. It will be of interest to know precisely what amount of training is expected on the part of those who carry out the treatment. Are they State-registered nurses, members of the Chartered Society of Massage and Medical Gymnastics, or bath assistants who have acquired a knowledge of the correct procedure by constant practice?—I am, etc.,

London, W.1, Feb. 1st.

M. B. RAY.

Inheritance of Mental Deficiency

SIR,—The letter of Dr. Ian D. Suttie (*Journal*, January 27th, p. 170) is a fair example of the bias which can be introduced into the discussion of a case of feeble-mindedness when an effort is made to avoid at all costs the imputation of inheritance. It is obvious that on the data available regarding this incestuous family nothing can be proved, so it becomes a case of adopting the most reasonable interpretation.

The original grandparents were mentally normal and produced a large family, of whom two sisters were mentally defective, and a brother finally developed general paralysis and dementia. The union of this brother and one of his sisters produced three children, two of whom were mentally normal at ages of 17 and 7 years. Now I know of no authority on the subject who denies that recessive factors are often involved in the inheritance of feeble-mindedness. Dr. Penrose certainly does not. Which is then the more reasonable—to assume that this explanation, which fits all the known facts, is applicable to this pedigree, or to make the highly improbable assumption that a feeble-minded mother and a father suffering from paralysis and dementia would create a better home environment than two normal parents? The question has only to be asked. The answer is sufficiently obvious.—I am, etc.,

King's College, London, Jan. 31st.

R. RUGGLES GATES.

Symbols in Pedigrees

SIR,—As I have received a few inquiries as to the meaning of the symbols used in my article "The Menace of Hereditary Blindness" in the *British Medical Journal* of January 20th I send the following explanatory key:

- = Normal female.
- = Normal male.
- = Defective homozygous female.
- = Defective homozygous male.
- ¹○ = Normal carrier (heterozygous female).
- ¹□ = Normal carrier (heterozygous male).
- ^{ca}□ = Died.
- ✕₅ = Died defective at age 5 years (female).
- ✕₃ = Found defective at age 3 years (male).
- = Miscarriage.
- ⊙ = Four normal females.
- ⊠ = Six normal males.
- ⊞ = Six children (normals) sex unknown.
- = One cyc only defective.

—I am, etc.,

London, W.1, Jan. 30th.

J. MYLES BICKERTON.

The Services

DEATHS IN THE SERVICES

Major William McEnea Snodgrass, M.C., R.A.M.C., of Lifford, County Donegal, died at the Royal Victoria Hospital, Netley, on February 1st, aged 42, of infection received while performing an operation on a Service patient. He was born on December 10th, 1890, and was educated at Trinity College, Dublin, where he graduated M.B., B.Ch., and B.A.O. in 1915. Subsequently he took the special diploma of the English Colleges in laryngology and otology in 1927. He joined the Special Reserve of the R.A.M.C. in 1915, as soon as he had qualified, and went to France with the Third Division before the end of the year. He served in the long-drawn-out battle of the Somme in 1916, when he was wounded, and received the Military Cross. In March, 1918, he was sent to Iraq, and then went to Persia and India. He took a permanent commission in the R.A.M.C., with the rank of captain, on December 18th, 1918, and became major on May 30th, 1927. He served in the Waziristan campaign in 1920 and returned to England in 1922. From 1925 to 1931 he served in Egypt, and on his return home was posted to Netley as oto-rhino-laryngologist. He leaves a widow and two children. The honorary secretary and treasurer of the Southampton Division of the British Medical Association (Dr. John Clayre) writes: Major Snodgrass had a charming personality, and was popular with all in the Service and his fellow-members of this Division. He was a keen sportsman and all-round athlete, and had played Rugby for Dublin University. Deep sympathy is felt for his widow and family.

Major Ram Chandra Malhotra, O.B.E., Indian Medical Service, died in India on December 22nd, aged 49. He was born on November 19th, 1884, and was educated at Edinburgh University, where he graduated M.B., Ch.B. in 1911. He also studied at University College, London, at Charing Cross Hospital, and in Dublin, and took the D.P.H. at Cambridge in 1914. After filling the posts of clinical assistant at the Brompton Chest Hospital and casualty officer at Charing Cross Hospital, he took a temporary commission in the I.M.S. as lieutenant on May 15th, 1915, and got a permanent commission on November 1st, 1920, being ranked as captain from May 20th, 1917. He attained the rank of major on October 18th, 1927. He served in the war of 1914-18, was mentioned in dispatches in the *London Gazette* of August 15th, 1917, and June 3rd, 1919, receiving the O.B.E. He recently held the appointment of assistant director of public health at Rawal Pindi.

Obituary

A. A. MONTAGUE, M.B.LOND., F.A.C.S.

Past President, Fiji Branch

All those who have, at any time during the past thirty years, lived in the Colony of Fiji will learn with deep regret of the death, on January 30th, of Dr. Aubrey Montague, formerly chief medical officer of the Colony. Aubrey Alfred Montague, who was 61 years of age, was born at St. Margaret's, Twickenham. He was educated at the City of London School, and then entered St. Thomas's Hospital. He qualified M.R.C.S., L.R.C.P. in 1896, and took the London M.B. in 1898. In 1925 he was made a Fellow of the American College of Surgeons. After holding an appointment as house-surgeon at Wolverhampton General Hospital he joined the Colonial Medical Service, and was appointed a Government medical officer in Fiji in 1898. In 1912 he was made senior medical officer, a position which carried with it the positions of resident medical superintendent of the Colonial Hospital and superintendent of the public lunatic asylum. On several occasions he acted as chief medical officer, and in 1922 he was appointed to this post, and made chairman of the Central Board of Health. A few months later he was nominated a member of the Legislative Council. After his retirement in 1930 he resided in Oakham, where he died after a month's illness, borne with great patience and fortitude.

Dr. Montague was for many years the outstanding figure in the medical profession of Fiji. He was president of the Fiji Branch of the British Medical Association from 1922 to 1930. He was devoted to his profession, and was very popular with his patients and with his colleagues. Many of the present staff of native medical practitioners were trained by him during his time at the Colonial Hospital, and during his term of office as chief medical officer the Central Medical School was greatly enlarged and improved. Dr. Montague was a man of sterling worth, and his simple, unassuming manner endeared him to all who knew him. His name will long be remembered in the Colony to which he gave his life's work. He leaves a widow and one son, who is now in the Government Medical Service of Fiji.

THE LATE SIR WILLIAM HARDY

The Regius Professor of Physic, University of Cambridge, writes:

It has been pointed out to me that amid the chorus of praise for the man and his work hardly anything has been said of Sir William Hardy's researches on leucocytes, and that I should repair this omission. I do so the more gladly because I was working under him at the time, and well remember the infectious enthusiasm with which those researches were pursued. He had already worked at the blood of invertebrates when Ehrlich's methods of staining the granular leucocytes appeared. He was quick to appreciate the value of this new aid to research, and, in conjunction with Kanthack, applied it first to working out the details of phagocytosis and then to the role of eosinophilia in bacterial infections and intestinal digestion. As I wrote in 1932, this work passed into undeserved oblivion, though the study of asthma, urticaria, and other allergic states has independently confirmed the accuracy of their views. But I remember that Hardy was rather nettled by Michael Foster's scepticism, though I believe that this scepticism caused him to re-examine the methods, and this led him to suspect that some of the histological appearances were artefacts, and thus, as Sir Gowland Hopkins has said, to his pioneer work on colloids. Kanthack's early death, at the age of 35, deprived pathology of a genius, but his partner was spared to enrich science in many ways, and not least by his magnetic power of inspiring a whole-hearted devotion to research in his pupils. Like his colleague Gaskell, he scattered ideas with a lavish hand for others to reap later, while he went on to fresh fields. To him life was always a great and exciting adventure.

W. LANGDON BROWN.

Medico-Legal

DUSTMAN'S DEATH: WIDOW'S APPEAL FAILS

The appeal by Mrs. Ada Edith Pattenden from a jury's verdict and judgement of Mr. Justice Horridge in the King's Bench Division (reported in the *British Medical Journal* of October 21st, 1933, p. 760) was dismissed by Lords Justices Scrutton and Maugham and Mr. Justice Talbot in the Court of Appeal on January 31st. In her action she claimed damages against Dr. Charles Beney in respect of the death of her husband, Henry Thomas Pattenden, alleged to have been caused by the exploding of a carbon dioxide gas cylinder.

Mr. J. D. Cassels, K.C. (for the widow), in the course of his argument, referred to Murray's Dictionary for a definition of the word "explosion." Mr. Cassels said his case never had been that the container burst. It was that there had been some failure of the article which caused the screw cap to come off with great violence, and so to injure the man holding it that he died.

Lord Justice Scrutton, in his judgement, said the Court could not interfere with the findings of Mr. Justice Horridge that the cylinder was not dangerous, and that there was no danger in handing it over to the dustman. With that finding the whole case for the plaintiff broke down. One had no reason to suppose that extraordinary treatment would be applied to cylinders handed over to dustmen in such circumstances. It rather looked as if the man had been trying to knock the cylinder cap off. "When you get to knocking off a cap, possibly with another cylinder, all sorts of things may happen that do not appear to be the natural result of handing these things over to be taken away by the dustmen." The appeal failed, and would be dismissed with costs. The other members of the Court concurred.

Universities and Colleges

UNIVERSITY OF OXFORD

At a congregation held on January 18th the degree of B.M. was conferred on J. A. Boycott.

UNIVERSITY OF LONDON

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

The tenth biennial Sydney Ringer Memorial Lecture will be delivered by Dr. A. S. Parkes, F.R.S., in the lecture theatre of University College Hospital Medical School on Friday, February 23rd, at 5 p.m. His subject will be "The Co-ordination of the Reproductive Processes," and Professor Herbert R. Spencer will be in the chair. The lecture is open to all qualified practitioners and medical students.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-ON-TYNE

With reference to the announcement in the *Journal* of January 27th (p. 176) of the special course of post-graduate instruction, the time of commencement of the course dealing with pulmonary tuberculosis and infectious diseases should be 3.30 p.m., and not 6.30 p.m. as stated.

UNIVERSITY OF GLASGOW

The Senate announces that Professor Andrew Hunter, M.A., M.B., B.Sc., has been elected dean of the faculty of medicine for the year 1934.

BRITISH COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At the quarterly meeting of the council, held on January 29th, with the president, Dr. J. S. Fairbairn, in the chair, the following were elected to the Membership of the College:

Margaret Anderson, G. S. Brown, F. W. Buddee, Charlotte Douglas, G. Griffiths, Kathleen Harding, L. G. Higgins, Gladys Hill, H. Leaver, J. C. H. Leicester, Jocelyn Moore, H. K. Pacey, P. Peltz, J. M. Scott, A. J. Wrigley.

Dr. Lucien de Zilwa (Ceylon) was admitted a Foundation Fellow (*in absentia*) and the following were admitted to the Membership (*in absentia*):

A. B. Nash, D. J. Malan, G. M. White, B. H. Watson.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

Further discussion of the Unemployment Bill occurred in the House of Commons this week. Other discussions concerned disarmament and safety on roads. The British Hydrocarbon Oil Production Bill and the Mining Industry (Welfare Fund) Bill were down for second reading. The House has passed the North Buckinghamshire Joint Hospital District Bill, and has sent the Wirral Joint Hospital District Bill to a Committee. Consideration of the Dye-stuffs (Import Regulation) Bill has begun in Committee. The London County Council (General Powers) Bill and other corporation Bills have received a second reading. On February 2nd the second reading of the Matrimonial Causes Bill was moved by Mr. Holford Knight and Dr. C'Donovan moved its rejection, and the debate was adjourned.

Drugs of the Barbituric Group

Sir JOHN GILMOUR told Dr. Howitt, on February 1st, that drugs of the barbituric group were included in Part I of the present poisons schedule, and were therefore subject to the full restrictions imposed by the Pharmacy Act, 1868, upon the sale of poisons. The question whether any further restrictions were desirable would be considered by the Poisons Board recently established under the Pharmacy and Poisons Act, 1933. Mr. D. GRENFELL asked if there was any system of inspection, and whether the Home Office had any officers to see that the Act was properly administered. He added that there were widespread complaints against the ease with which these drugs could be obtained. Sir JOHN GILMOUR replied that the law made certain provisions. The new advisory board would investigate whether further steps were required. Sir FRANCIS FREMANTLE asked when the House would receive some report from the Poisons Board. Would there be an early report on this disturbing feature? Sir JOHN GILMOUR asked for notice of this question.

Preponderance of Silicosis in South Wales

On February 6th Mr. E. BROWN, replying to Mr. D. Grenfell, said he was informed by the Home Office that since June 1st, 1931, when the coal mining industry first came within the scope of the General Medical Board under the Silicosis Compensation Scheme, 432 men in the industry had been certified by the Board to have been disabled or to have died from silicosis or from silicosis accompanied by tuberculosis; and that 385 of these cases occurred in the South Wales coalfields. Earlier comparable figures were not yet available. This extraordinary preponderance of cases in South Wales presented a very difficult problem, and no satisfactory explanation could as yet be given. As regarded the more highly siliceous rocks, it was already compulsory to take dust-prevention measures in drilling operations, while, as regarded other Coal Measure rocks, drilling machines were not used to any substantially greater extent in South Wales than in other coalfields. The application of a general measure of the kind proposed to drilling in all kinds of stone would not appear, therefore, to be an appropriate remedial measure.

Mr. E. BROWN told Mr. Tinker, on the same day, that the greatest depth at the Parsonage Colliery, Leigh, Lancashire, at present was about 3,850 feet. No complaints by workmen had been brought to the notice of his Department. As a result of intensive study it had been possible to effect some improvement of the working conditions in the district where the temperatures were highest, and all possible efforts would continue to be made to effect further improvement. As regarded the question of amending legislation, he referred the hon. member to previous replies.

Blood Test in Drunkenness.—Sir JOHN GILMOUR told Captain Erskine-Bolst, on February 1st, that he doubted the value of the new blood test system in cases where drunkenness was an element in a criminal charge. He had no power to require any person to submit to it.

Prices of Insulin.—Replying to Mr. D. Grenfell, on January 31st, Mr. SHAKESPEARE said that throughout 1933 the price per 100 units to the consumer of two of the three brands of British insulin was 2s., of the third 1s. 8d., and of the principal imported brand 1s. 5d. He had no information on the quantities sold. On January 11th, 1934, the price of two British brands was reduced to 1s. 10d., and of the third to 1s. 5d., with corresponding reductions in wholesale prices. There had been no change in the price of imported insulin since the additional import duty was imposed. Colonel COLVILLE told Mr. Leckie, on the same date, that the position with regard to prices of insulin was being closely watched.

Cost of Mental Deficiency Service.—On February 5th Mr. SHAKESPEARE informed Sir Basil Peto that the total cost falling on public funds in respect of the Mental Deficiency Service might be taken as having been approximately £1,875,000 in 1931-2. Exact information as to the amount included in this figure in respect of institutional treatment was not available.

Poor Relief Recipients.—Sir HILTON YOUNG told Mr. McEntee on February 1st that the total number of men, women, and children in receipt of poor relief in England and Wales, excluding rate-aided patients in mental hospitals, persons in receipt of domiciliary medical relief only, and casuals, on January 13th, 1934, was 1,406,076. The corresponding figure for the same date in 1933 was 1,391,185.

Medical Defence Service Recommendations.—Mr. MORE-BELISHA informed Captain Elliston, on February 6th, that he regretted that, owing to the time required for necessary consultation with the Government of India on the report of the Warren Fisher Committee, he was not yet in a position to announce the decisions of H.M. Government on the recommendations in reference to the Royal Army Medical Corps and other medical services of the defence forces. He hoped, however, that it would be possible to do so at an early date.

Accommodation for Hop-pickers.—Replying, on February 2nd, to Mr. Alan Todd, Sir HILTON YOUNG said he had seen a report of the Staffordshire County Council's Education Committee on the conditions obtaining in the hopfields in Herefordshire and Worcestershire. He was communicating with the Staffordshire County Council for the hitherto undisclosed names of the farms about which complaints were made. The responsibility for supervising the accommodation provided for hop-pickers rested with the local sanitary authorities. His officers inspected the more important hop-growing areas from time to time. Any serious defect in the arrangements made for hop-pickers was brought to the attention of the local authority responsible.

Asphyxia from Oxy-acetylene Heater.—Replying, on February 1st, to Captain Erskine-Bolst, Sir JOHN GILMOUR said that the death of William McDonald of Limehouse was due to asphyxia after being in charge of operations with an oxy-acetylene super-warmer in a ship. An account of the death would be published in the series of notes on industrial accidents, which had a wide circulation among firms likely to be affected. This account would draw attention to the danger now revealed and the necessary precautions. He would consider whether any other action was needed.

Deaths at British Celanese Factory.—On February 6th, replying to Mr. Emrys-Evans, Sir JOHN GILMOUR said he was advised that it could now be stated that the particular chemical responsible for the deaths of the workmen employed at the British celanese factory at Spondon was diethylene-dioxide, otherwise known as dioxan. Investigations were proceeding as to the degree of toxicity of this substance with a view to determining under what conditions, if any, it could safely be used.

Experiments on Animals.—Mr. DUFF COOPER, on February 6th, told Captain Erskine-Bolst that no dogs or horses were used for poison gas experiments at Porton, Cambridge, or elsewhere in Great Britain, in 1932 or 1933. During 1932 83 animals were used at Porton for chemical defence experiments and 190 for experiments in connexion with the subject of safety in industry. The corresponding figures for 1933 were 72 and 343 respectively. No experiments on animals were carried out elsewhere in connexion with chemical defence.

Noise Offence Prosecutions.—In reply to Mr. McEntee, on February 1st, Sir JOHN GILMOUR stated that preliminary figures showed that, during 1933 in England and Wales, 9,653 noise offences of all classes in connexion with motor vehicles were dealt with by prosecution. The Minister of Transport was taking up the matter with the manufacturers in order to secure an abatement of this nuisance.

Indians and University Courses.—Sir S. HOARE has informed Sir W. Davison that it is for the authorities of the Indian universities and not for the Government to decide whether any limitation shall be imposed on the numbers of Indians taking a university course with the object of obtaining a degree. He doubts whether it will serve any useful purpose to obtain a report from the French Colonial Office, which for some time has limited the output of college-trained men.

Small-pox in British India.—On February 6th Sir SAMUEL HOARE told Mr. Groves that the number of registered deaths from small-pox in British India for the last twenty years for which final figures were available were as follows: 1911, 58,535; 1912, 89,357; 1913, 98,155; 1914, 76,590; 1915, 83,282; 1916, 60,642; 1917, 62,277; 1918, 93,076; 1919, 136,077; 1920, 101,329; 1921, 40,446; 1922, 40,836; 1923, 44,084; 1924, 53,380; 1925, 85,986; 1926, 117,066; 1927, 118,197; 1928, 96,123; 1929, 72,884; and 1930, 72,813.

Housing in Scotland.—Mr. SKELTON states that the recommendations of the Departmental Committee on Scottish Housing, including the proposal to set up a Scottish Housing Corporation, are receiving careful consideration, but the Secretary of State is not yet in a position to make any announcement on the matter.

Notes in Brief

During 1933 a total of 67,246,032 meals were provided by local education authorities in England and Wales for children in schools. The percentage of free meals was 80.6. During December, 1933, 277,918 children were fed.

Since a Select Committee reported in 1930 on the abolition of the death penalty there have been twenty-nine executions in England and Wales, all the offenders being males.

Medical News

At a meeting of the Pharmaceutical Society of Great Britain, to be held at 17, Bloomsbury Square, W.C., on Tuesday, February 13th, at 8.30 p.m., a lecture on "The Influence of some Nutritional Factors in Disease" will be given by Dr. Edward Mellanby, F.R.S., secretary of the Medical Research Council and lately professor of pharmacology in the University of Sheffield. Members of the society are invited to bring friends.

A meeting of the Paddington Medical Society will be held at Great Western Royal Hotel, Paddington, W., on Tuesday, February 13th, at 9 p.m., when Dr. Robert Forbes, Deputy Medical Secretary of the British Medical Association, will give an address on "Medical Ethics," followed by a discussion.

At the annual general meeting of the Institute of Heating and Ventilating Engineers, to be held on Wednesday, February 14th, at the London School of Hygiene and Tropical Medicine, Keppel Street, at 2 p.m., Sir Leonard Hill will read a paper on infra-red rays and comfort.

A meeting has been arranged by the National Council for Mental Hygiene for Wednesday, February 14th, at 5 p.m., at 11, Chandos Street, W., when Dr. Doris Odlum will read a paper on mental hygiene in the changing world.

Sir Frederick Hobday will give a lecture, illustrated by lantern slides and films, on "Our Animal Friends as Patients" at the Princess Elizabeth of York Children's Hospital, Glamis Road, Shadwell, E., on Friday, February 16th, at 8.45 p.m., when Brigadier-General Sir Hill Child will be in the chair. Visitors are invited.

A post-graduate course in industrial diseases will be held at the medical faculty of Halle University from February 26th to March 3rd. Further information can be obtained from Professor Clausen, Augenklinik, Halle.

The Fellowship of Medicine and Post-Graduate Medical Association (1, Wimpole Street, W.) announces that the fifth lecture-demonstration at 11, Chandos Street, by Dr. Clark-Kennedy, on February 13th, at 2.30 p.m., will deal with constipation; the subject of the sixth lecture, on February 20th, will be diarrhoea. Four ante-natal demonstrations will be given at the Royal Free Hospital by Dame Louise McIlroy, on Fridays at 5 p.m., from February 16th to March 9th. Six demonstrations on the interpretation of pyelograms will be given by Dr. Mather Cordiner at 8 p.m. on Tuesdays and Fridays, from February 13th to March 2nd. A whole-day course in medicine, surgery, and the specialties will be given at the Prince of Wales's Hospital from February 19th to March 3rd. A demonstration on the treatment of recent and old fractures will be given by Mr. Alan Gairdner at St. George-in-the-East Hospital, on February 27th, at 2.30 p.m. Other forthcoming courses include medicine, surgery, and gynaecology at the Royal Waterloo Hospital, March 5th to 24th; proctology at the Gordon Hospital, March 5th to 10th; week-end course in clinical surgery at the Royal Albert Dock Hospital, March 10th and 11th.

The annual dinner of the Hospital Almoners' Association was held on February 3rd at the Hans Crescent Hotel. Miss C. Morris, chairman of the Association, presided, and the guests included: Miss Lloyd Still (matron, St. Thomas's Hospital), and president, International Council of Nurses); Miss Louisa Martindale (senior honorary surgeon, New Sussex Hospital, Brighton); Mrs. Rendel Wyatt (joint warden, Manchester University Settlement, and late secretary, Institute of Hospital Almoners); Dr. Ian Grant, medical superintendent, Royal Infirmary, Glasgow; and Mr. H. M. Hallsworth, professor of economics, Armstrong College, Durham University.

At the monthly meeting of the Central Midwives Board for England and Wales held on February 1st approval as lecturers was granted to Dr. Percy Vernon Davies, Kingston and District Hospital, Dr. Beatrice Mary Joly, Cheltenham District Nursing Association, and Dr. Robert Watson, F.R.C.S.Ed., Walton Hospital, Liverpool.

Dr. W. J. Turrell, physician in charge of the electrotherapeutic department of the Radcliffe Infirmary, Oxford, ex-president of the Electrotherapeutic Section of the Royal Society of Medicine, and honorary Fellow of the American Electrotherapeutic Association, has received at the hands of Dr. Norman E. Titus of New York, who is now visiting London, the "Gold Key" awarded to him at the last annual meeting of the American Congress of Physical Therapy. This distinction is the highest award in the United States for original research and distinguished services in the field of electrotherapy. Among other recipients have been Professor d'Arsonval, the doyen of French specialists in electrotherapy, Professor Harvey Cushing, for electrotherapy in brain surgery, Professor Claudius Regaud of the University of Paris, and Dr. Gustav Bucky of New York. The presentation to Dr. Turrell was made at a dinner offered to Dr. Norman Titus by Dr. Howard Humphris, to whom the award was made by the congress of 1932. Among those present at the dinner were Sir Henry Gauvain, Sir Leonard Hill, Sir William Willcox, Dr. R. King Brown, Dr. J. B. Mennell, and Dr. Franz Nagelschmidt.

The Lord Chancellor has recently added the name of Dr. Louis C. S. Broughton to the Commission of the Peace for the County of Worcester.

The King has granted Major A. G. Biggam, O.B.E., R.A.M.C., authority to wear the Insignia of Commander of the Order of the Nile, conferred on him by the King of Egypt in recognition of valuable services rendered as professor of clinical medicine in the Egyptian University.

The World Congress of Milk will be held in Rome on April 30th, when sixty countries will be represented.

A bronze bust of Professor Einthoven of Leyden, who died in 1927, has recently been unveiled at Bad Nauheim.

Dr. William His, professor of internal medicine at Berlin University, has been awarded the Goethe medal by President von Hindenburg.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology
Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER
(Advertisements, etc.), *Articulate Westcent, London.*

MEDICAL SECRETARY, Medisera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshough Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUÉRIES AND ANSWERS

England's Debt to Scotland

Dr. J. H. McCulloch (Colvend, Dalbeattie, Scotland) would be grateful for biographical or other information bearing upon contributions of Scotsmen, past and present, to medical science in England.

Treatment of Chronic Herpes

"**VESICLE**" (Norfolk) writes: I wonder if any readers could give me advice as to the treatment of a lady, aged 60, with chronic herpes frontalis. The original attack was five years ago. Since then the pain has been constant, with repeated outbreaks of spots on the head. Her life is made unbearable, and no treatment seems to be of any avail.

Threadworms and Printers' Devils

Corrigendum

A grotesque blunder was made last week in our printing office, for which apologies are due to readers in general and to Colonel W. P. Macarthur in particular. At page 224, in a footnote to one of the letters making suggestions for the treatment of threadworms, Colonel Macarthur was misquoted as recommending "the use of two grains of santonin and half an ounce of calomel by mouth." We feel sure that this will have been recognized by every reader as a misprint for *half a grain*.

Income Tax

Production of Bank Pass-book

"**JUNUS**" has been asked by the inspector of taxes to produce his bank pass-book for scrutiny. Can this request be enforced?

* * The inspector has himself no statutory authority to require evidence in support of a taxpayer's return, but if the return is not accepted and an assessment in excess of the amount of the return is made, the taxpayer's only remedy is to appeal to the Commissioners, and that body has a very wide discretion as to what evidence it requires for the purpose of the appeal. It may be worth while pointing out that the pass-book forms part of the material which a professional accountant would commonly expect to be available to him when preparing accounts for a practice, so that its relevance on an income tax matter must, in general, be admitted.

Contribution to Superannuation Fund

"**I. T. X.**" obtained relief from 1921 to 1928 on that portion of the premiums (in connexion with a university superannuation fund) which had been borne by her. Since 1928 she has borne, and has had allowed for income tax, the whole amount of the premiums. The authorities now say that those allowances were incorrect, and are seeking to adjust the allowances for the last five years.

* * There is no allowance for premiums paid in respect of deferred annuity policies parallel to that in respect of life

assurance. There is, however, a partial form of relief governed by Section 32 of the Finance Act of 1921, which provides for the allowance of payments made by employees to approved superannuation funds. "**I. T. X.**" was evidently entitled to relief while an employee of the university concerned, but if she left that employment in 1928 her subsequent payments would not be allowable for income tax.

LETTERS, NOTES, ETC.

Prescription of Hypnotic Drugs

Dr. G. NESBITT-WOOD (Hastings) writes: I am afraid "Pharmacist's" suggestion (*Journal*, February 3rd, p. 224) for the limitation of hypnotic drugs of the barbitone group—namely, marking the prescription "Not to be repeated"—is of little use so long as a number of lesser chemists are prepared to sell them over the counter like so many sweets. A patient of mine during a long illness received sodium barbitone, and, unknown to me at the time, developed a perfect passion for the drug. One night I was called to find her in a coma, and the whole matter came out. Secreted round her room were eighty tablets of sodium barbitone, each of 5 grains, which she said she had bought from the same chemist in the space of three days. When I visited this man he blandly showed me his book recording the sale of twenty tablets only, and as it was his word against the patient's I could take the matter no further than request him not to serve her again. I was later informed that when she again tried to obtain supplies at his shop he suggested that she should change her doctor and so obtain official sanction for more. Since then I have had a two years' struggle with her, and she has never again divulged the name of the chemists from whom she gets her tablets, but I know that she visits Eastbourne, Brighton, Lewes, Rye, and other places, and gets supplies at all of them, and from time to time gets them in this town. She says some chemists have offered to send her all she needs by post. Her husband caught out one chemist in Brighton, who was as cool as you like over it. "If we refused you, our rivals would not," was the gist of his remarks. As this woman has made four attempts on her life with sodium barbitone (she is perfectly sane), it would appear that regulations such as those governing morphine might be advantageous. I must, of course, state that my patient admits that all the first-class pharmacies in this town have refused her point blank when she could not produce a proper prescription.

Disclaimer

Dr. W. H. D. CROOK (Wonford House, Exeter) writes: In a recent issue of a Sunday newspaper there is an article containing a statement about me which is not only completely inaccurate but physically impossible. At the end of the article is what appears to be an interview with me. This "interview" consisted of a telephone trunk call, in the course of which I particularly asked the newspaper concerned not to publish my name, and emphasized the fact that I wanted no publicity whatever. I had no idea that they intended to report any part of this conversation.

Solute for Foot Baths

"**OTIUM**" (Liverpool) writes: Frequently one orders a foot-bath containing sodium carbonate for tired and swollen feet, and for arthritis of the tarsus or ankle. For some time I have used, instead of the carbonate, the well-known soap powder "persil," one tablespoonful to the gallon, and have found it to be more efficacious than the former, and much less severe on delicate skins. In like proportion a full bath can be taken in cases of lumbago, sciatica, and various suitable arthritic conditions, with most beneficial results.

Raised Intraocular Tension

Corrigendum

The second sentence of **Dr. Victor Parvus's** letter under this heading (February 3rd, p. 215) contained a superfluous word which changed his meaning. The phrase should read: "but, from an ophthalmological point of view."

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 40, 41, 42, 43, 46, 47, and 48 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 64.

THE HUNTERIAN ORATION

Delivered before the Royal College of Surgeons of England on February 13th

BY

SIR CUTHBERT WALLACE, K.C.M.G., C.B., F.R.C.S.

CONSULTING SURGEON TO ST. THOMAS'S HOSPITAL

As a member of the Court of Examiners to this College I have on many occasions sat in the Council Chamber before the portrait of John Hunter while examining a candidate. It was natural in the circumstances that the question should arise as to what Hunter would have thought of the knowledge displayed by the candidates. Would he have been astonished at the ignorance or pleased with the knowledge displayed? Would he have been amused or irritated when the examinee expressed total ignorance of John Hunter and the work that he did? Such musings led me to wonder what would have been Hunter's opinion of our present-day education. From there again my thought turned to a comparison of the circumstances and conditions under which medicine is learnt and practised to-day and one hundred and fifty years ago. It is on this subject I would offer a few reflections to-day.

The life of Hunter and that of the surgeon of the present day can each be divided into three similar periods. The first is that of education or preparation, the second a period spent in war service, and the third a period of practice and fulfilment.

HUNTER'S EDUCATION

Hunter, when a youth, was uncouth and ill-tempered. He refused to be educated in the orthodox way. Instead of attending school he roamed the countryside. This time was not altogether wasted; he was even then pondering the reason for the things he saw about him. It is probable that to this obscure period of his life can be traced the origin of the Earl's Court menagerie, and those letters to Jenner demanding all sorts of queer things, such as bats, eels, cuckoos, fossils, and salmon spawn. These letters show better than anything else the nature and diversity of the man's interests. Hunter referred to this period of his life in the following words, which seem to sum up the motive of his life:

"I wanted to know all about the clouds and the grasses, and why the leaves changed colour in the autumn. I watched ants, bees, birds, tadpoles, and caddisworms. I pestered people with questions about what nobody knew or cared anything about."

Towards the end of this period, and shortly before he left for London, Hunter paid a visit to a brother-in-law, who was a cabinet-maker. Whether Hunter ever actually practised the trade is immaterial at the moment. Jesse Foote, Hunter's detractor, intending to say something nasty, turned this visit to his purpose, and declared that Hunter was a carpenter who had deserted the *chisel*, the *rule*, and the *mallet*, to take up the *knife*. This is a gibe that could not be levelled against the present-day surgeon, certainly not against those that practise our most comprehensive specialty. If surgery has become more scientific it has in some directions become more mechanical. It is not, perhaps, to be wondered at that Foote seized his opportunity, but it is curious that great pains have been taken to prove that Hunter had never acquired the art of the carpenter. Surely there is nothing derogatory in a knowledge of the proper use of tools, a knowledge that is one of the things that distinguish man from the brute beasts.

When I came across this passage in Foote's book it made me ask myself how the manual skill of any surgeon, or perhaps I had better say how my skill, compared with that of a joiner or fitter? Despite what one reads in books and the daily press of the manual dexterity of the surgeon, I came to the conclusion that I had better refrain from pushing the comparison, and took refuge in the thought that the power and worth of the surgeon lies more in his judgement than in his technical skill: the science is greater than the art.

With all that is happening in medicine, I think we are apt to forget the magic that Nature exercises when in the course of a few days she turns the primitive joinery of the surgeon into the thin, firm, and supple scar. Perhaps it was this process which Hunter had in mind when he said, "Original inflammation constitutes a part of the animal economy and is probably inexplicable." Even to-day we imperfectly understand the stimulus that starts the healing process.

MEDICAL EDUCATION

Hunter's medical education commenced in 1748, when, at the age of 20, he joined his brother and commenced to dissect. He at once shed his waywardness, and commenced a life which was a monument of diligence: the round peg had found a round hole.

His medical studies extended over some nine years, but were discontinuous, and, in addition, interrupted by periods of ill-health. In the summers of 1749 and 1750 he studied under Cheselden at the Military Hospital at Chelsea. In 1751 he put in some time at St. Bartholomew's under Pott. In 1754 and 1756 he took a course of surgery at St. George's, and in the latter year was appointed house-surgeon, which post he held for five months. Between the two courses of surgery at St. George's Hospital he went to Oxford, but soon decided that a classical education was not for him. In 1760 Hunter may be described as having qualified, as he was appointed staff surgeon in His Majesty's Army. During all these years he was working in his brother's school.

To understand the opportunities that the times offered to a student of surgery one has to recall the nature of the medical education of the period. It was almost entirely of the apprenticeship system, a great part of which system remains to this day in England. The student usually served a matter of five or seven years, after which, if he wished to practise in London, he had to be admitted into a corporation. To do this he had to obtain the recommendation of somebody of position, or undergo a viva voce examination, which was apt to be more brutal than efficient.

Although there were differences between the hospitals, there was little or no systematic instruction given at these institutions. The lectures that were available and open to the student were delivered by various people at the halls or as private ventures on their own premises. The courses, which varied much in length, were often given late in the afternoon or early evening, at a time when the present-day student expresses himself as tired and mentally unreceptive. The lectures were apparently open to the public, thus showing that the laity were even then interested in medicine.

Some courses were devoted to single subjects, but others, to our present-day ideas, seem a strange jumble of subjects, consisting as they did of anatomy, comparative and human, animal economy or physiology, operative technique, fractures and dislocations, midwifery, and bandaging.

Anatomy was taught by diagrams, models, and sometimes by preparations. It is to be remembered that William Hunter improved the teaching by affording opportunity for the actual dissection of the body. It was part of John's business to arrange for the bodies. Bandaging seems to have been considered important and interesting; nowadays it is beneath the dignity of a student. Thus we have an interesting example of the changing value of subjects in medical education, of which we are rather apt to lose sight.

Even with all this variety of subjects the lectures were considered to require a little spice, as we find that the demonstration of a monster was sometimes added as a special attraction. John Hunter was very interested in monsters, and recognized that they fell into different classes; he also knew that the prenatal period was a history of ancestors.

When Hunter became a surgeon to St. George's Hospital he tried to arrange that lectures should be delivered at the hospital to the pupils and apprentices. He was strenuously opposed by his colleagues, who asserted that lectures were of little use, thus expressing an opinion which, after a hundred and fifty years, is again being freely stated. Hunter, however, hinted that the reason lay in another direction, and that the real cause of the opposition was the fear of the staff to expose their own ignorance. He carried the battle further and accused his colleagues of taking money from their pupils and apprentices and doing nothing to earn it.

This effort of Hunter, though at first abortive, helped the movement that was gaining ground to take medical education out of private hands and establish it at the great hospitals. He appears at last to have converted his colleagues, as in 1793 we find that they complained that the students had to go for their anatomy to Windmill Street, for their midwifery to Golden Square, for their chemistry, *materia medica*, and practice of physic to Leicester Fields, and thus lost considerable time. The recognition of the disadvantage of spreading medical education over several institutions is interesting in the light of developments that are taking place to-day.

EDUCATION IN 1760 AND 1934

Hunter never served an apprenticeship, so that his education may be described as less controlled than was usual even at that time. The instruction he received seems very fragmentary and discontinuous; in fact it might almost be described as an interlude to his work in his brother's school. One must remember, however, that in this school Hunter must have been brought into contact with many men and listened to their opinions and conversation. He thus was undergoing all the time a type of education that was really suitable to a man who was receptive, independent, and capable of being his own tutor. Some might take the view that Hunter succeeded in spite of his disadvantages, but to me it seems more the truth that the method of education suited the man.

Although the length of medical education was not dissimilar to that of the present day the circumstance of that education was very different. On the one hand we have an education where everything depended on the student's own perseverance, receptiveness, and determination; no ordered course of study; the man chose his own teachers and hospitals, and very often went abroad for a time. At the present time all is ordered and ordained. First of all a certain standard of general education is

demanded; then a course in which the subjects, the sequence in which they are to be taken, and the length of time devoted to each, are accurately defined, even in some cases to a matter of hours. There are signs, too, that there will be further subdivisions of this time, so that in the end there will be but little opportunity for self-education, mental digestion, or reflection. In fact, we are moving away from the academic and to trade-school ideas of education. It seems also possible that even after graduation or qualification the curriculum will still maintain its grip upon the individual to the time of his death.

A short while ago, when the increasing complexity of subjects demanded more time, and it was evident that the proportion of man's life devoted to medical education could not be increased, an attack was made on the time usually given to general education in the secondary schools. To judge by the ability of many students to put their ideas clearly and succinctly on paper, and remembering Hunter's defect, this seems a mistaken policy, and that it would be wiser to let the schoolmaster conduct his own business in his own way.

No one will deny that medical education has benefited by the guidance of a central body. On the other hand, a common curriculum has some disadvantages. It is a compromise and, as such, has been and probably always will be a subject of criticism. It tends to produce a sameness in the schools and universities. It takes no heed of individuals.

It is possible that, in the desire to improve the standard of medical education, we have gone too far in centralization of control. A common curriculum means that no one education authority is doing what it really desires or believes best. Would it not be better to allow greater discretion so that individual schools could develop different characteristics?

WAR PERIOD

Hunter resigned his house-surgeonship at St. George's in 1756, apparently on account of ill-health. In 1759 he had inflammation of the lungs at a time when he was studying the lymphatic system. In 1760 he was appointed staff surgeon in the Army, and in 1761 sailed for Belleisle as surgeon on the staff. The reason of his going is not clear; probably it was a question of health or money rather than of adventure. He took part in the capture of the island and in the bloodless campaign in Portugal in the following year.

The total wounded were about 500, and, as the care of these was divided among the surgeons of the expedition, the number that came under Hunter's charge must have been moderate. In fact, we find that he soon had spare time and spent this studying "life" or "animal economy," and later on in Portugal he made observations on geology.

He arrived in Belleisle with some definite opinions as to the proper way to treat wounds, though whence he had acquired that knowledge is not clear. He lost little time in expressing disapprobation of his colleagues' treatment as well as of his colleagues themselves. Whether this outburst was the result of Hunter's rather irritable nature or of an attempt to assert himself, or whether it was justified, it serves to remind us that the war of 1914 was similar to the war of 1761, in that it was productive of criticism of one's colleagues.

Hunter prepared nothing about his war experiences for publication until many years had passed, thus showing at all events a remarkable literary continence for a surgeon who had seen active service. This work, which was not published until 1794, in the year following his death, states that the war had given him the opportunity of studying inflammation, about which he says he had constantly thought during the years which had elapsed.

If one substitutes "infection" for "inflammation" the problem that interested Hunter and the surgeons in the Great War was remarkably similar. Even to the end of the Great War the surgeon was without the means of combating established infection, though by the rough-and-ready way of excising the wound while still only contaminated he succeeded in preventing infection.

This pamphlet, like much of Hunter's writing, is a difficult document to read and to understand. One wonders why it never saw the light till so many years had elapsed. It contains nothing very arresting. I doubt if it was of great use to the surgeons that went to the war which was again starting, but it contains matter which is of interest to a generation that has known a great war. Just as in the Great War, amputations and the opening of wounds were exercising the minds of the surgeons.

It was debated whether an amputation should be done while the patient was "hot from the fight" or as a secondary procedure. Hunter supported the latter; it was given a trial, but eventually abandoned on account of a high mortality. The second point of dispute was whether the almost universal practice of opening all wounds should be continued. Hunter made the very good remark that it should only be done if there were an object to be gained, but did not indicate clearly what this object was except to say that it was not necessary to search for foreign bodies. His influence apparently led to wounds being only opened when inflammation had set in. In the South African War the wounds were for the most part left untouched and did well. In the World War the opening of the wounds was the situation of the matter. From this it would appear that it is largely worth to enter upon any war with a fixed idea as to the proper treatment.

Hunter also made the interesting remark that there was nothing peculiar about war wounds; they were simply confused wounds. He expressed the opinion that it was a pity that they were regarded as something apart. The term "military surgery" is, I think, an unfortunate one. There is only one surgery—namely, the best that the time has produced. The only difference between surgery in peace and surgery in war is that in the peace you are enabled to do what is right and in war you have to strive, in adverse circumstances, to do what you know is right, that is, to approximate your practice to that of civil life.

EFFECT OF THE WAR ON SURGERY

It does not seem that Hunter's war had any material effect on the art of surgery or on the conditions under which it was practised. The number of surgeons, the number of wounded, were small, and Hunter published nothing at the time.

In like manner, turning to the war of our generation, I should say that it introduced little improvement in the practice of the art. It is true that it gave rise to much activity in mechanical contrivances and that it popularized methods and apparatus already in use. It revived, for a time, the early days of the antiseptic period, and gave us a whole rainbow of coloured antiseptics, but finally proved the Listerian principle that the best way to combat infection was to prevent the lodgment in the body of the infective agent.

A large number of doctors were taught a specialized kind of surgery, and working under supervision, acquired considerable dexterity. This led to the idea that surgery was a matter of technique rather than of judgement. In the departments of medicine that affect surgery the war emphasized the value of prophylaxis in tetanus; it gave rise to the serum treatment of anaerobic infections, and

it demonstrated the value of restoring the blood volume and gave the birth of the chemical theory of a shock.

One hundred and fifty years ago medical science was represented almost entirely by the physician, the surgeon, and the general practitioner. Since that date medicine has split into many branches, some concerned with the actual practice of the art and others with subjects more or less allied, and lastly, others that only here and there touch the healing art. Necessity and the stimulus of the war brought all these branches again into contact. This running together again of the sciences which had grown out of medicine was the most important effect of the war; it was a union which, in a humble way, was represented in the person of John Hunter.

EFFECT OF WAR ON ENVIRONMENT OF SURGERY

Apart from the influence of the Great War on the art of surgery and the stimulus that it gave to research, it may have a great future effect on what may be called the machinery or administration of medicine. It emphasized what had obviously long been a fact—that a disease might be a mischance that could no longer be diagnosed and efficiently combated by the knowledge and skill of one individual. It demonstrated what could be done by co-ordination of effort, when there was a good directorate and the workers were willing to subordinate themselves. It led to the thought that if a great army could be so efficiently kept in health or treated when sick, why should not a nation in peace be kept in health and treated when sick by a similar organization? And lastly, the advantages of a salaried post over the continual struggle and anxieties of private practice began to loom large in the minds of many.

PERIOD OF PRACTICE

Hunter returned to England in 1763 and found himself with only his half pay and no private practice. From this time his life was one continual labour. Astley Cooper said of him: "He was the last in the laboratory or study at night, and the first there in the morning, allowing himself very little time for repose." The daily programme was something as follows. Up before five in the morning and engaged in dissection or study. Then the care of his private practice and attendance at the hospital. Dinner in the late afternoon, a short sleep followed by a lecture, and again work in the laboratory until the small hours of the morning.

Such a day would be beyond the powers of most men, but when a terrifying disease brought no cessation, one's admiration goes out to such determination and bravery. He was elected a Fellow of the Royal Society in 1767, and was appointed surgeon to St. George's Hospital and a member of the Corporation of Surgeons in 1768. About 1772 he abandoned anatomy and commenced his lectures on the theory and practice of surgery.

Hunter's life at this time was very similar to that of many young surgeons after the Great War, in that his life was divided between hospital duties, teaching, investigations, and what private practice came to hand. Hunter accomplished an immense amount of work, but it has to be remembered that hospital duties were very light, consisting only of one or two visits, and there was no teaching.

Although operations are not the whole of surgery, and less in those days than now, some idea of the amount of time demanded by a hospital appointment may be gathered from their number. I have no direct evidence of the number in Hunter's time, but a computation can be made by some figures quoted by Godlee in his life of Lister. According to these figures, in the era immediately preceding Lister the number of operations in the large

hospitals was about one a day, and about one-fifth of these were amputations. It is probable that they were less in Hunter's time.

It is interesting also to try and picture the scope of Hunter's surgery and the relative importance of the different subjects. Samuel Sharp, F.R.S., a pupil of Cheselden and a surgeon to Guy's Hospital, wrote a book on operative surgery which went through ten editions. The seventh edition, published in 1758, contains 288 pages. The first 54 pages are devoted to the treatment of wounds, inflammation, abscesses and ulcers; 20 pages to hernia; 69 pages to genito-urinary diseases, 43 of which are given up to lithotomy; 26 pages to the trepan; 20 pages to the eye; and 20 pages to amputations. The other subjects mentioned are empyema, encysted tumours, scirrhus of the breast, bronchotomy, extirpation of tonsils, nasal polypi, hare-lip, wry-neck, paracentesis, fistula-in-ano, aneurysm, inoculation. None of these receive more than nine pages. In Jonathan Bell's *System of Surgery*, published about the same time, one finds a very similar distribution of interest, but considerable space, almost a third, is devoted to injuries. This list shows the scope of surgery and where the chief interest lay. It also shows that the field was limited, although it included subjects now the domain of the specialist.

All that Hunter did and wrought and the admiration he aroused in his disciples is a matter of history. There is no doubt that his ideal of experimental investigation led eventually to modern medicine. One may, however, try and gauge what immediate effect his work produced on his art; was it at all comparable to that produced by Lister?

This can be done to a certain extent, at all events, by a study of the books and lectures in the years following his death.

Astley Cooper, the surgeon to Guy's Hospital, delivered a series of lectures at St. Thomas's Hospital. The date of these lectures must have been just before the year 1825, at which date Guy's and St. Thomas's dissolved partnership. A study of these lectures shows no great alteration in scope of surgery or in relative values, with one exception, and that was the adoption of the Hunterian ligature. Cooper affords striking evidence of the utility of this operation as he says in one of the lectures that formerly any patient who had been cured of a popliteal aneurysm could always gain a living by showing himself at a hospital, but now Mr. Hunter had deprived these lucky ones of their means of livelihood.

In 1847, South, a surgeon to St. Thomas's Hospital, brought out a carefully annotated edition of *Chelms's Surgery*. In this work Hunter is referred to again and again: in point of fact, in an index of subjects on which authorities are quoted the space devoted to Hunter far exceeds that given to any other person. A perusal of this book again fails to show any striking alteration in the interest of the surgeon. The early editions of *Erichsen's System of Surgery*, published about 1860, tell much the same tale, though the trend of thought is more modern.

The reason that surgery made no great bound after Hunter as it did in Lister's time can, I think, be explained. In the first place Hunter left behind him no one at all comparable to himself. In the second place a very large part of his work was the study of normal processes. In this connexion I may again quote Astley Cooper:

"Physiological knowledge is of the utmost importance to the professor of surgery; this gives you knowledge of the healthy functions, and thus enables you better to understand the nature of diseased action. This was the rock on which Hunter stood, admired by the wise and abused by the ignorant."

Though, as Cooper says, such knowledge is necessary for the proper understanding of disease it cannot in itself explain the departure from normal. Again, a great deal of Hunter's labours were purely biological, and could not be applied to medicine.

The problem of inflammation was one that interested Hunter more continually than any other, and was one that closely touched medicine. It was recognized that inflammation was the agent of repair, and therefore a process inherent in the individual, but the inflammation that arose apart from this was the crux that caused pages of involved language, and in the end remained unexplained.

There is a third reason. To one educated in the post-Listerian period it is almost inconceivable that a system of medicine unpeopled by bacteria, moulds, or protozoa, and unilluminated by a knowledge of the cellular nature of the body, could advance with rapidity. It is not to be expected, therefore, that the years that came immediately after Hunter would show a great forward movement. It seems as if medicine was awaiting the advent of Virchow to produce his cellular pathology, of Pasteur to solve the riddle of many diseases, of Lister to free the surgeon's hands, and of anaesthetics to diminish the fear of operations. It may be said that Hunter prepared the way to a new medicine rather than that he created a new world of surgery.

SPECIALISM

The problem of specialism and of the specialist, either from a practical or from an educational point of view, was not acute. Whether the physician or surgeon was to be considered as specialist depends on the individual point of view. The modern enthusiast for specialism would say that the general physician and surgeon are interesting relics of an honourable past; while the modern student, I expect, regards medicine, surgery, and obstetrics as natural divisions of medicine rather than specialties. The Ministry of Health regards them as the three bases of the healing art.

In those far-off days there were apothecaries, physicians, and surgeons. Some of the surgeons were possessed of special skill in lithotomy and couching for cataract, and to that extent were specialists, but, with these exceptions, the modern specialisms were still unseparated. The surgeons were taking their places alongside the physicians largely owing to the influence that Cheselden and Pott exerted, but even as late as 1825 we find Astley Cooper complaining of the interference of the physicians. This protest was caused by the prescription of a cathartic by a physician for a case of compound fracture which was under the care of Mr. Cooper. Obstetrics were passing from the midwives into the hands of those that confined themselves to that branch. It is interesting to note that there was a complaint that the instruction of students in this subject was defective.

Of late years specialism has grown apace. The old specialisms had their origin in the necessity for the possession of a special skill in the treatment of a special part. The later specialisms tended to be founded on special knowledge of a particular organ or a special disease, and the latest specialisms have origin in none of these things. Specialism has come to stay if only for the reason that the public demands it and the authorities that rule our education recognize it.

Specialism is a form of division of labour or of knowledge, and as such should lighten the burden of the student working for a qualification. Unfortunately the opposite is the case, and the advent of a new specialty means a new burden. This will continue until it is recognized that specialism is a post-graduate function. It can even be said that general practice is a specialty, not because medicine and surgery as practised in hospital

are different from those in general practice, but for the reason that the conditions under which they are practised are so different. It might be helpful if a hospital could arrange with some of its sons to take qualified students for a limited period as apprentices, thus returning, in a way, to an old custom. It is a curious thing that medicine is the only profession where a recently qualified man is spoken of as a finished product. In the Church you have to be a deacon before a bishop, and in the Army a subaltern before a colonel.

QUACKS AND QUACKERY

The definition is difficult, but everyone knows what is meant by a quack. Nothing since the days of the Hunters has altered so little as this question. William Hunter was apprehensive that he might be judged one; John Hunter had no objection to meet them, and on one occasion tried unsuccessfully to induce the owner to part with a secret prescription of an ointment. Lettsom waged a war against them, but was beaten in the end. Some were complete impostors; many worked in the realms now ruled over by specialists, treating a class of case which the doctors for one reason or another were unwilling to undertake.

The borderline between regular and irregular practice was ill defined, because there was no easy means of finding out whether or no a person had had a medical training. To distinguish a registered from an unregistered practitioner is now easy, but the facilities offered by the *Medical Register* have not in any way diminished the quacks; in fact, they are as flourishing as ever, and in some instances have copied the doctor and established a curriculum and a register. The high and low in the land seek their advice.

It is apparently impossible to persuade the public that the doctor is disinterested in his attitude toward irregular practice. Only recently I heard an individual high up in the academic world, who was discussing the subject, express the view that he had taught too many undergraduates to have any opinion of the value of the letters after a man's name. Under these circumstances would it not best become the profession to take its stand on the preamble of the Medical Act, and only ask to be clearly distinguished from those who have not had its medical training?

RESEARCH

Hunter demonstrated the fruitfulness of the experimental method, both in medicine and in biology; he also gave an example of the pitfalls that surround this method. If he were to come back and survey the field of medicine nothing would, I think, astonish him more than the position that research occupies to-day. He would wonder at the progress of medicine, but this feeling would be nothing to that inspired by the expansion of the effort to get forward and lay bare the secrets of Nature. In his time investigation was a simple matter. To-day, though there is still work to be done by a man with no special training, research, in many instances, requires a special education, a laborious study of the subject, and a skilfully thought-out plan.

The difference that exists between the times may perhaps be best brought out when we compare the rather simple investigations of Hunter's with those of Laidlaw and Dunkin for the *Field Distemper Fund*. These two investigators, starting with a disease of which the clinical symptoms had to be determined, worked for ten years, and expended £55,000 before they brought the disease under control. Research now works in a framework of careful organization. In fact, the organization has become a profession in itself. Here I would pay a tribute to Walter Fletcher, a man of great attainments, of far vision

and foresight, a man who devoted his great powers to help the worker.

In those days there was little or no aid for the worker, who was self-supporting, and had to look to his own pocket to provide the means for investigation or experiment. John Hunter spent his fortune on his museum. To-day, partly by private beneficence and partly from Government grants, there are large sums of money available which not only help the part-time worker, but support a small army of men who devote their whole time to their work.

Connected with research is the diffusion of knowledge. At the present time this is rapid, even to the ends of the earth; there are many professional societies and periodicals without end. In those days knowledge had to spread in the main by personal contact or communication. There was the Royal Society, but no exclusively medical associations except in Edinburgh and Paris. The naval surgeons seem to have been the first to supply the need in 1748. This society received original communications, which it bound and distributed to members. It also invited well-known people to lecture before it. Both William Hunter and Samuel Sharp did so. It is to its credit that it recognized a tendency to prolixity in medical matters, and instituted a censorship of the material it published.

In 1783 Hunter and Fordyce founded the Society for the Improvement of Medical and Chirurgical Knowledge, which lasted for a few years. This was followed in 1785 by the *Lycæum Medicinæ Lomblinense*, which met in the New Museum in Carter Street, and seems to have been in the nature of a research club. In 1773 Lettsom and a group of friends had founded the Medical Society of London, which, after many early struggles, has come down to our times.

THE FUTURE

It is impossible to stop the progress of Medicine, but progress may be helped or hindered by the conditions under which medicine works. In Hunter's time the profession consisted of individuals very loosely governed as regards education or conduct. It had very little contact with the State. The Elizabethan Poor Law was still in existence, and the State paid little heed either to preventive or to therapeutic medicine. To-day we find a highly organized profession; and organization, while it offers the possibility of resistance, also facilitates negotiations. The State controls a highly efficient preventive and therapeutic medical service; it is taking a greater and greater interest in education. There are some 20,000 doctors in receipt of public money. The war produced within the profession a considerable body of opinion favourable to a still greater control of medicine by the State. In the years to come we may be individuals linked together by a desire to stamp out or cure man's ills or we may be a swarm of workers in a national hive. In either case let us hope that the diligence, the curiosity, and the energy of John Hunter will be our guide.

The annual report of the National Institute for the Blind for the year 1932-3 is characterized by special attention to the excellent results obtained through special treatment and education. Illustrations are given of the extent to which independence in living can often be achieved, and there are many examples of the various activities which have an economic as well as a moral significance. The massage department records a very successful year, and there is now an advanced course in electrotherapeutics, comprising diathermy and high-frequency work. The new electrical clinic has assisted students training for the medical electricity examinations, and has been of great benefit to hospital patients.

INFLUENZA: ITS SEQUELAE AND TREATMENT*

BY

JAMES TORRENS, M.D., F.R.C.P.,

SENIOR PHYSICIAN, ST. GEORGE'S HOSPITAL

It is obvious that in one evening's discussion only the fringe of so large a subject can be touched upon, and I am faced at the onset with the very real difficulty of deciding not so much what to say as what to leave out in the short time at my disposal. I have therefore thought that it may make for simplicity if I restrict my remarks to some general considerations on what we understand by the term "influenza," and how this disease behaves to the community at large as well as to the individual sufferer from it.

Influenza, then, is an infective disease capable of producing an infinite variety of clinical manifestations and differing in severity within the widest possible limits; it is always present in a sporadic and usually mild form, but it tends to assume epidemic proportions at frequent intervals. Such epidemics may occur in the winter months, when the clinical manifestations are for the most part catarrhal and respiratory, or they may occur in the summer months, when there seems to be a greater tendency to implication of the nervous or alimentary systems. When epidemic proportions are reached—and this happens every year or two—there seems to be a tendency for a similar clinical type to develop in the great majority of cases of that particular epidemic, but this is not invariable, and in every considerable epidemic we find examples of an entire household struck down within a few days, each member of which may exhibit a different clinical picture of disease. In addition, however, to the constant mild sporadic cases (the so-called influenza cold), and the frequent more severe but not too serious epidemics, influenza gathers its forces together every thirty to forty years, exalts its virulence, and sweeps a continent, or even the entire globe, like a veritable destroying angel. These pandemic visitations spread with the precise speed of human intercommunication, and their range is only limited by the movements of humanity, so that at the present time, with aeroplane and other transport facilities, no part of the earth is likely to escape the malign "influence." When once a populated area has been exposed to infection the spread throughout that area is extremely rapid, till within three or four months every susceptible person has been laid low and the pestilence has moved on. Unfortunately, influenza—in marked contrast to measles and poliomyelitis—does not seem to provide any lasting degree of immunity to its victims, though there seems to be enough immunity persisting to prevent a second attack during the same epidemic; but countless individuals have undoubted influenza, though often of widely differing clinical type, every year throughout twenty or thirty years or longer.

HISTORICAL

Records show that there have been some fifteen major epidemic visitations of pestilence to Europe in the last 500 years, and that, although the clinical types have varied greatly, each of these would, or should, now be recognized as influenza. There is no reason to suppose that such epidemics have only been manifest for some 500 years. Indeed, there is every reason to believe that they have occurred throughout the ages, but have been limited in extent by the relative lack of intercommunication between one populated area and another which obtained in bygone centuries. Thus the epidemic argues

and the sweating sicknesses of the Middle Ages, as well as certain so-called epidemic dengues, can fairly be regarded as influenzal, while the "trousse-galant" which swept through France in 1529 appears to have been a form of encephalomyelitis developing a few months after all Europe, except France and Italy, had been subjected to the fourth epidemic of "sweating sickness." This name was translated into English as "stup-gallant," and used later for the fifth epidemic of "English sweat." The malady known as "coqueluche" was widespread throughout France during the months of February and March, 1510, and again several times during the sixteenth century, and seems to have been a form of epidemic influenza, which we still see, characterized by an absence of catarrhal symptoms but an intolerable pain in the head, back, and shoulders. The actual name "influenza," as also "la grippe," seems first to have been used about 1745. It was used by the Italians much in the same sense that it was used by Job in the Old Testament—"Canst thou bind the sweet influences of Pleiades, or loose the bands of Orion?"—save that the "influence" was far from sweet.

EPIDEMIOLOGY

An important point in connexion with the major epidemics of influenza is the fact that they are preceded and followed by lesser outbursts of epidemic disease for several years, and that such lesser outbursts are not of the same clinical type as the pandemic visitation when it does arrive. Further, it would seem that before and after a major influenzal epidemic there are seen in epidemic form various diseases of the nervous system, of which the most consistent seem to be poliomyelitis, cerebro-spinal meningitis, and encephalomyelitis (lethargic or spasmodic). It is stated that cerebro-spinal meningitis and encephalitis follow the influenza after an interval of a year or more, while poliomyelitis is more often seen a year or two before the influenza, but this is by no means invariable. In this connexion it is interesting to note that Hippocrates described a serious epidemic of paraplegia occurring one year at Thiasus in the winter months, and followed with the commencement of spring by an epidemic of "burning fever" or influenza. This suggests that influenza was behaving in very much the same manner 2,500 years ago as it is to-day. I wonder if Hippocrates failed to observe and note accurately any single manifestation of disease that came within his purview!

If we consider the epidemic happenings in the few years before and after the pandemic of 1918-19, it is possible to see how accurately the events of those years conform to the epidemic concept briefly described above. For example, there was a considerable epidemic of gripe through the United States in 1915. This was closely followed by a notable epidemic of poliomyelitis in and about New York. In 1915-16 there was a considerable incidence of purulent bronchitis with heliotrope cyanosis in the Army at home and abroad. In the spring of 1918 there was a widespread, but not severe, epidemic of febrile disease associated with a rash, and generally thought to be influenza, in Europe, while in the autumn and winter of 1918-19 the pandemic visitation occurred. A year later there was a considerable amount of much less severe influenza, and the first cases of encephalitis lethargica were described. These persisted till 1924-5, and then gradually died away. There was then a period of relative rest from influenza and kindred manifestations until 1929. It is interesting to note here that just as the influenzal encephalitis in the early 'nineties was thought to be due to botulism, so were the earliest cases of lethargic encephalitis in 1919 given the same name. Similar mistakes have very often occurred before. If we accept as correct this picture of influenza and its habits in relation to the community as a whole, it is easy to

* A paper read before the Westminster and Holborn Division of the British Medical Association, December 14th, 1933.

forecast that somewhere between 1945 and 1955, if not before, there will be another pandemic visitation, which will afflict the entire world. And unfortunately, in view of our present ignorance concerning the causation of influenza, there is very little we can do to prevent this catastrophe.

INFLUENZA AND THE INDIVIDUAL

I have tried to sketch briefly the epidemic course of influenza and to show that, if you consider it in sufficiently large a pattern, it repeats its programme with considerable uniformity at approximately regular intervals. I will now turn for a moment to the way in which influenza affects its individual victims; there is no disease so protean in its manifestations, and it is only because these different manifestations have been so clearly connected with epidemic waves of disease that it has been possible to recognize them all as manifestations of the same fundamental malady. At the same time three main types can be distinguished—respiratory, gastrointestinal, and nervous. These may merge the one into the other, or they may be utterly distinct. A great majority of all cases show catarrhal affections to a greater or less extent; but such are by no means necessary, and the symptoms of influenza may be strictly confined to the nervous system, with no vestige of catarrh from start to finish. In the absence of an epidemic the difficulties of diagnosis of the less common variants of influenza are very great, and it is not uncommon to suspect such widely different conditions as cerebral tumour, tuberculous or other forms of meningitis, enteric fever, food poisoning, and acute or subacute rheumatism when the cause is really one of influenza; conversely, in the presence of an epidemic, these various diseases may quite well be labelled influenza, and their real nature overlooked until it is too late. I do not think that detailed consideration of the clinical course of an influenza attack comes within the scope of this discussion, but I think it is important to try and arrive at some idea as to the nature of the infection which is such a scourge to industrial humanity—an infection which can vary in intensity from that of an innocuous cold in the head to that of a pestilence which kills in a few hours, which confers so transient an immunity, and which can present so diverse a clinical picture.

It has been suggested, if I understand rightly the views of the late Dr. Crookshank, that no single bacillus or no single virus can be found or postulated to fulfil the requirements of this disease, and that influenza pandemics may depend on telluric or cosmic happenings, the nature of which we cannot even guess at, whereby from time to time humanity as a whole is rendered liable to invasion by various secondary infections, streptococcus, pneumococcus, Pfeiffer's bacillus, etc., against which there is for the time being a greatly lessened power of resistance; but it does not seem necessary to invoke witchcraft or celestial influences to explain influenza. It is, of course, true that the actual and ultimate cause of death in influenza is usually one or other of these secondary organisms, but the spread of an epidemic, and its posting character—limited in scope and rapidity only by the facilities of human travel—and its extraordinary power of case-to-case infective transmission when once it has reached a new area, strongly suggest to me the existence of a basic communicable specific infective agent. I shall never forget watching influenza spread from bed to bed round two wards full of cases of gunshot wounds of the chest in 1918 in France, immediately following the admission of a new patient who had influenza as well as a trifling wound of the thorax; no man escaped in these wards, and half the total number perished. Within a fortnight the entire hospital of 2,000 beds was ravaged, and from twenty to thirty deaths were occurring daily.

The relative immunity of the medical and nursing staffs was striking, as showing the influence of general hygiene and ample fresh air in limiting case-to-case infection.

THE CAUSAL AGENT

A vast amount of work has been done on the bacteriology of influenza, though for many years the work of Pfeiffer and the discovery of his bacillus in 1892 was accepted as indicating the true cause of influenza; but Pfeiffer's bacillus is not the cause of influenza, despite the dictum of Wassermann, "Wo Influenzen da Influenzenbazillen"—a remark which only serves to show the danger of dogmatic utterance in the realm of medicine. If Pfeiffer's bacillus were the cause of influenza, it would be found in a very high percentage of epidemic influenza cases either before or after death, just as *B. typhosus* can be demonstrated post mortem in every case of fatal typhoid fever. Neither in life nor after death can Pfeiffer's bacillus be found in as many as 40 per cent. of any large number of cases of influenza, while in many series of cases it is not found at all. Further, Pfeiffer's bacillus is known to exist in saprophytic form in many tuberculous cavities and other lesions, or in perfectly healthy persons, though undoubtedly it can at times assume a state of high pathogenicity. Neither has any other single organism been found present with sufficient constancy in different influenza epidemics to justify it being labelled as the cause of influenza. It is hard to believe that, if influenza is due to any microscopically visible bacillus or coccus, it would not have been identified with reasonable certainty by now, considering the numerous investigations into this question during the last forty years.

In view of the frequency with which the haemolytic streptococcus is found in the blood stream, or in the lesions of fatal cases of influenza in certain major epidemics, it might be thought that influenza is merely a variant manifestation of the streptococcus; but again many fatal cases do not show any streptococcus infection—in some it is a pneumococcus, in others, a mixed infection with Pfeiffer's bacillus in predominance, while simple uncomplicated influenza does not seem to show any special tendency to streptococcal associations. One is thus forced to conclude that the occurrence of these demonstrable bacteria, although causing the death or serious symptoms of the individual, is really only a secondary and complicating infection, the way for which is paved by the incidence of an unidentified primary influenza infective agent. That death in influenza epidemics is not due to the influenza itself but rather to a secondary and complicating infection has been believed for many years, and Broussais in 1837 wrote in the *Paris Lancette*: "What have necropsies shown? With regard to the entity of la grippe they have shown nothing. When the sick man dies of it, it is no longer la grippe, it is a complication! But how can you say that this man would have had this affection of which he has died, if he had not had la grippe?" Broussais was tilting at the morbid anatomist Andral, who, because post mortem he could find nothing characteristic *per se* of influenza, declared that the disease only existed in the imagination of the physician. Nevertheless, Broussais' view expresses very much what is thought to-day: "You do not often die of influenza itself; you die very often in times of epidemic influenza of complicating infections that you would not have acquired but for the fact that you were first afflicted with influenza."

If, then, the cause of influenza is not to be found among the microscopically visible bacteria, we must proceed to search for it among the ultra-microscopic filter-passing viruses, which would bring it into line with measles, poliomyelitis, and probably many other diseases.
